Abstract

Bellare and Rogaway [ACM CCS '93] introduced the famous *random oracle* model as a “paradigm for designing efficient protocols”. This paradigm has led to several highly efficient and widely used in practice constructions, such as the *RSA Full Domain Hash* signature scheme (RSA-FDH). Unfortunately, little is known about the security of the resulting schemes in the standard model, when the random oracle is replaced by a concrete function. In particular, it is unknown whether we can reduce their (standard model) security to any “natural” assumption.

Prior work has shown several “uninstantiability” results for various abstractions of RSA-based schemes, where the RSA function was replaced by a random permutation. These abstractions, however, do not allow either the reduction or the hash function instantiation to use any algebraic properties of RSA function, such as the multiplicative group structure of \mathbb{Z}_n^* . In this work we develop new techniques which rule out such algebraic instantiations, focusing specifically on the case of RSA-FDH. We show that it is impossible to reduce the security of RSA-FDH to any natural assumption, provided that *the construction and the reduction treat the multiplicative RSA group \mathbb{Z}_n^* in a black-box way*. To the best of our knowledge, this restriction is satisfied by all positive results for RSA-based signatures, including standard model constructions of Gennaro et al. [EUROCRYPT '99], Cramer and Shoup [ACM TISS '00] and Hohenberger and Waters [CRYPTO '09].

As our main technical (and conceptual) contribution, we show how to adapt the powerful “short description” paradigm of Gennaro and Trevisan [FOCS '00] to the “generic group” setting. This paradigm is typically used to rule out one-way permutations based reductions, showing that their security proofs would imply a (provably impossible) way to “compress” a random permutation. In our setting, the reduction has access to a random group G isomorphic to \mathbb{Z}_n^* , and can use the algebraic properties of G . Still, we show that such a reduction must “know” the factorization of n (and, hence, does not “benefit” from the signature forger), since otherwise it can be used to “compress” our group G .

We demonstrate the optimality of our negative result, at least in some sense, by showing that the RSA-FDH signatures *can* be proven secure in the standard model, *under the standard RSA assumption*, provided the number of signing queries is a-priori bounded.

1 Introduction

Bellare and Rogaway [2] introduced the famous *random oracle* (RO) model as a “paradigm for designing efficient protocols”. When following this paradigm, one first builds a provably secure scheme assuming that an access to a *random* function is given, and (possibly) assuming some “standard” hardness assumption (e.g., factoring is hard). Then it instantiates the scheme by replacing the random function with some *concrete* “hash function” (e.g., SHA-1). The intuition underlying this paradigm is that a successful attack on the resulting scheme should indicate (an unexpected) weaknesses of the hash function used. This paradigm (also known as the random oracle heuristics) has led to several highly efficient and widely used in practice constructions, such as the *RSA Full Domain Hash* signature scheme (RSA-FDH) [2] and *RSA Optimal Asymmetric Encryption Padding* scheme (RSA-OAEP) [3]. Typically, however, very little is known about the security of popular schemes resulting from the above paradigm. In particular, it is unknown whether we can reduce their security to any “natural” assumption.

In this work we study the security of such schemes, while focusing on “group based” constructions (as we explain below), and in particular study the security of RSA-FDH signature schemes. The RSA signature [33] is one of the most elegant and well known signatures schemes. It is extensively used in a wide variety of applications, and serves as the basis of several existing standards such as PKCS #1 [34]. In its “textbook” form, the signature σ of the message m is simply $\sigma = m^d \bmod n$, which can be verified by checking if $\sigma^e \equiv m \bmod n$, where e is the public RSA exponent, and $d = e^{-1} \bmod \phi(n)$. Of course, the textbook variant is completely insecure, as any σ is a valid signature of some message $m = \sigma^e \bmod n$. The traditional fix known as RSA-FDH, is to hash the message m before signing it using some “appropriate” hash function h (i.e., $\sigma = h(m)^d \bmod n$). The key question is how to instantiate this function h ?

Bellare and Rogaway [2] showed that in the random oracle model, where h is modeled as a truly random function (freely available to all the parties including the adversary), RSA-FDH is secure assuming that the (standard) RSA assumption holds. When considering actual instantiation of h , a moment reflection shows that all known security notions for hash functions, such as collision-resistance or pseudorandomness, do not appear to help. In fact, even more “esoteric” notions, such as perfect one-way hash functions or verifiable random functions [5], are not sufficient as well. On the other hand, no significant attacks on RSA-FDH signatures are known when h is instantiated using popular “cryptographic hash functions”, such as SHA-1. This gave rise to the following important question, which is the main focus of this paper.

Is there an instantiation of RSA-FDH signature scheme (specifically, of hash function h) that can be proven secure under a natural assumption?

We start by reviewing what is currently known about the question, and then describe our contribution.

1.1 Known Results

It is well known that in the general case the random oracle heuristic is false. Specifically, there exist schemes secure in the random oracle model that cannot be instantiated by any concrete hash function [8, 9, 28, 18, 4]. Most counter-examples of this kind, however, are artificial, and do not shed much light on the question we study here. A more relevant result to our question is that of Dodis et al. [13] who concentrate on a generalization of RSA-FDH signatures, known as *Full Domain Hash* (FDH) signatures. In such signatures the signer has access to an arbitrary trapdoor

permutation f , and sets $\sigma = f^{-1}(h(m))$.¹ The main result of [13] rules out proving the security of an instantiation FDH, by reducing it to the one-wayness of f (or more generally, to any assumption on f that is satisfied by a random trapdoor permutation). The impossibility result of [13] does not capture, however, reductions that use additional assumptions about f . In particular, it is very likely that if a proof of security of some instantiation of RSA-FDH does exist, then it does use the *algebraic properties* of the RSA function. To demonstrate this point, we present (see Section 1.2) an instantiation of RSA-FDH under the standard RSA assumption, that is secure as long as the number of signing queries is a-priori bounded. Our reduction is black box, and uses the algebraic properties of \mathbb{Z}_n^* .² In addition, the “RSA-based” signatures [16, 11, 22], which can be proven secure in the standard model (but, alas, no longer have the simple syntax of the RSA signature), critically use the algebraic properties of the RSA function. Finally, even in the random oracle model, tighter security bounds are sometimes achieved using the algebraic properties of RSA (cf., [10], as compared to the generic proofs from trapdoor permutations [2, 39]).

Other relevant impossibility results are the “signature paradox” of Goldwasser, Micali, and Rivest [19] and the impossibility result of Paillier [29]. These results are only more restrictive than that of [13], and, in particular, do not rule the above mentioned constructions we see in practice, where the algebraic properties of the RSA function are used.

We briefly mention other known results concerning the uninstantiability of popular signature and encryption schemes that can be proven secure in the random oracle model. Paillier and Vergnaud [30] showed that many popular discrete log based signatures (including *ElGamal*, *DSA* and *Schnorr*) *cannot* be reduced to the discrete log assumption in the standard model, using the so called “algebraic” reductions. Such reductions, however, are very limited comparing to the reductions we do see in practice. In the realm of factoring/RSA-based CCA encryption, Paillier and Villar [31] and Brown et al. [7] showed uninstantiability results analogous to above-mentioned RSA signature result of Paillier [29]. Finally, Kiltz and Pietrzak [23] presented an uninstantiability result for proving CCA-security of RSA-OAEP encryption [3], which is in a sense analogous to the FDH result of [13] discussed above. Unfortunately, this result was recently found to be seriously flawed, as acknowledged by the authors of [23].

1.2 Our Result

Our main result generalizes the result of [13] to the case of RSA-FDH. Informally, we prove the following fact:

Theorem 1.1 (Informal). *It is impossible to reduce the security of an instantiation of RSA-FDH to a “natural” assumption (and in particular to the hardness of RSA), provided that the reduction treats the multiplicative RSA group \mathbb{Z}_n^* and the potential adversary in a black-box way.*

In Section 3 the meaning “treating the multiplicative RSA group \mathbb{Z}_n^* in a black-box way” is realized using the notion of *generic groups* [36, 27, 25].³ Roughly, it means that nothing is assumed

¹We mention that the same result of [2] also shows that these signatures are secure in the random oracle model.

²This usage is crucial, since [13] showed that even *one-time* security of *general* FDH signatures cannot be black-box reduced to the one-wayness of the trapdoor permutations.

³We mention that while term “generic group” usually comes with a bad “reputation”, much like the term “random oracle”, our usage of generic groups is different. Rather than using the generic group to justify some non-standard security assumption, or even worse, use it in the *design of the scheme*, we only use the generic group modeling to argue *impossibility* of a much wider class of reductions than what was possible with prior work.

about a group element, apart from what was revealed through the performed group operations (i.e., multiplication, inverse and equality check). In particular, an algorithm that treats \mathbb{Z}_n^* in a black-box way should perform equally well given oracle access to any group isomorphic to \mathbb{Z}_n^* (without knowing the isomorphism).

Discussion. To the best of our knowledge *all* known positive results on building “RSA-type” signatures (including the standard model constructions of [16, 11, 22], and, certainly, the random-oracle based schemes) treat \mathbb{Z}_n^* as a black-box, and only use its multiplicative structure. Thus, although our results still do not rule out certain types of constructions/reductions, they seem to cover all successful reduction techniques utilized to date (in contrast to the prior state-of-the-art results of [13, 29]). Of course, it would be great to remove any restriction on the black-box reduction. Such a result, however, seems beyond our current capabilities, as it would likely uncover a surprising weakness in the existing instantiations of RSA signatures (e.g., PKCS #1 [34]).

A limitation of the above result is that it assumes that the key generation algorithm outputs a prime exponent e with non-negligible probability. We note, however, that this is the case for the standard RSA assumption, and in fact some implementations prefer to use only prime exponents e .

Additional results. First, we notice that our proof technique immediately gives an alternative proof to the equivalence of RSA and factoring over generic groups, firstly proven by Aggarwal and Maurer [1].⁴ Second, as we already mentioned, we obtain the following positive result, which, in a sense, matches our negative result.

Theorem 1.2 (Informal). *Under the RSA assumption, for every polynomial t there exists an instantiation of RSA-FDH that is existentially unforgeable against $t(k)$ signing queries (where k being the security parameter). Furthermore, the reduction treats the group \mathbb{Z}_n^* and the potential adversary in a black-box way.*

We note that our construction is a generalization of RSA-FDH schemes, where the hash function h is chosen as part of the public key (and not fixed for all public keys). Unfortunately, we have little hope that this natural generalization can be instantiated for unbounded number of queries, since our impossibility result also rules out these types of reductions.

1.3 Our Technique

We believe that our technique to prove our main result (Theorem 1.1) is also interesting in its own right, since this is the first negative result capable to handle *general* “algebraic” reductions.⁵ On a very high level, our proof follows the approach of Dodis et al. [13], used to prove that there exists no fully black-box reduction from (general) FDH signature schemes to the one-wayness of random functions. [13] defined an oracle **Forger** relative to which no FDH signature scheme is secure, yet **Forger** does not help inverting a random function. In more detail, on input $(h, \{\sigma_i\}_{i \in [t]})$, **Forger** checks that (1) $\{\sigma_i\}$ are valid signatures for the messages $1, \dots, t$ (i.e., $f(\sigma_i) = h(i)$ for every $i \in [t]$, where f is the random function), (2) the evaluation of $h(1), \dots, h(t)$ does not query f on

⁴The result of [1] also generalizes to “generic rings”. As we stated, though, getting this result for generic groups was not our goal, and the result was obtained as a simple corollary illustrating the power of our techniques.

⁵The related result of [30] also considered what they called “algebraic” reductions. However, those reductions were of extremely particular kind, highly tailored to their application.

any element of $\{\sigma_i\}$, and (3) t is at least equal to $|h|$ – the description size of h . If positive, **Forger** returns the signature of 0 (i.e., $f^{-1}(h(0))$).

It is clear that **Forger** can be used to break the existential security of any FDH scheme: the attacker uses **Sign**, the signer of the scheme, to compute $\{\sigma_i\}_{i \in [t]}$ for some $t \geq |h|$, and then calls **Forger** on $(h, \{\sigma_i\})$, where we assume without loss of generality that condition (2) above holds with respect to this query (otherwise, faking a signature *without* **Forger** is easy). On the other hand, [13] showed that an efficient algorithm (with oracle access to f , but not to **Sign**) cannot provide all these signatures. Thus, **Forger** is useless in these settings, and in particular a black-box reduction (i.e., algorithm) cannot make use of **Forger** for inverting a random function, proving the main result of [13].

Intuitively, **Forger** is useless for an algorithm with no access to **Sign**, for the following reason. Fix some efficient oracle-aided algorithm R and let $\{0, 1\}^n$ be the domain of the random function f . Since a random function is one way, the only elements that R can invert are those elements it previously received as answers to its f -queries. Hence (since f is random), R only knows how to invert *random* elements inside $\{0, 1\}^n$. Since it takes at least t bits to describe t random elements in $\{0, 1\}^n$ (actually, it takes tn bits) and since the evaluation of $h(1), \dots, h(t)$ does not query f on elements inside $\{\sigma_i\}_{i \in [t]}$, there must exist $h(i) \in \{h(1), \dots, h(t)\}$ that R does not know how to invert, and thus cannot provide a valid signature for the message i .

Moving to our setting, we focus for concreteness on fully black-box reductions from RSA-FDH to the hardness of RSA (i.e., such reductions use the multiplicative RSA group \mathbb{Z}_n^* and the adversary in a black-box way). The blackboxness in the RSA group tells us that such a reduction should work with respect to any group isomorphic to \mathbb{Z}_n^* . In particular, it should work well with respect to the group $\pi(\mathbb{Z}_n^*)$, obtained by renaming the elements of \mathbb{Z}_n^* according to a random permutation π over \mathbb{Z}_n^* (i.e., $a \cdot b$ is defined as $\pi(\pi^{-1}(a) \cdot \pi^{-1}(b) \bmod n)$).

Given the above understanding, the first attempt would be to define **Forger** analogously to that of [13]. Namely, on input $(n, e, h, \{\sigma_i\}_{i \in [t]})$, **Forger** checks that (1) $\sigma_i^e \equiv h(i)$ for every $i \in [t]$, (2) the evaluation of $h(1), \dots, h(t)$ does not compute σ_i for some $i \in [t]$, and (3) $t \geq |h|$. If positive, **Forger** returns the signature of 0 (i.e., $h(0)^d$, for $d = e^{-1} \bmod \phi(n)$, where all group operations are over the group $\pi(\mathbb{Z}_n^*)$).

We would like to argue that if π is chosen at random, then the only way to make a non-aborting query to **Forger** is via using **Sign**, the signer of the scheme. It would then follow that **Forger** is useless for an algorithm R that has no access to **Sign** (and in particular to a black-box reduction). It turns out, however, that in our settings such R *can* make non aborting calls to **Forger**. The issue is that unlike in the setting of [13], R can make use of the algebraic structure of \mathbb{Z}_n^* to construct a non-aborting query to **Forger**. For instance, R can compute $\{j^e\}_{j \in [\ell]}$, and assuming some reasonable mapping M from $[t = \ell^2]$ to $\{j \cdot k\}_{j, k \in [\ell]}$, let $h(i) = M(i)^e \bmod n$ and $\sigma_i = M(i)$. Since the evaluation of $h(1), \dots, h(t)$ does not query an element of $\{\sigma_i\}_{i \in [t]}$, it follows that $(n, e, h, \{\sigma_i\}_{i \in [t]})$ is a non-aborting query.⁶ Alternatively, if R can break the RSA assumption over $\pi(\mathbb{Z}_n^*)$ (say, if it knows the factorization of n), then it can set $h(i) = i$ and compute $\sigma_i = h(i)^d$ (using the factorization of n to compute d).

Fortunately, we manage to prove that a non-aborting query of R is either “degenerated” (as in the first example) or indicates that R knows the factorization of n . To handle the first case, we change **Forger** to identify and abort on degenerated queries. Where we also show that it is easy to

⁶Note that to describe h it suffices to describe the set $\{j^e\}_{j \in [\ell]}$. Thus $|h| \in O(\ell \log n)$, which is smaller than t for large enough ℓ .

forge a signature with respect to a degenerated h (i.e., h that is part of a degenerated query), even *without* the help of **Forger**. Namely, we show that there is no secure RSA-FDH scheme relative to the modified **Forger**. We then show that with respect to this modified **Forger**, one can efficiently extract the factorization of n from an algorithm that produces a non-aborting query. It follows that for any efficient algorithm R with oracle access to **Forger**, there exists an efficient algorithm, with no access to **Forger**, that emulates R^{Forger} well. In other words, we prove that **Forger** is useless for the class of efficient algorithms with no oracle access to **Sign**.

Proving the above intuition is the main challenge of this work, and we achieve that using a novel adaptation of the Gennaro and Trevisan [15] short description paradigm, described below, to the generic groups realm.

1.3.1 The Gennaro and Trevisan short description paradigm and its adaption to generic groups

Loosely, Gennaro and Trevisan [15] show that an efficient algorithm that inverts a random function too well, can be used to give a too short description for a random function (and thus cannot exist). This elegant approach has turned to be an extremely powerful approach for proving impossibility results in the random functions realm, which typically imply black-box impossibility results for one-way functions/permutations based constructions. While the Gennaro and Trevisan paradigm (from now on, the GT paradigm) has several extensions (e.g., [17, 38, 21, 20, 32]), all are given in the random functions realm.

We would like to apply a similar approach for arguing that an algorithm that makes a non-aborting query to **Forger**, can be either used to factor n , or to “compress” the random permutation π (which defines the group $\pi(\mathbb{Z}_n^*)$). Since compressing π is impossible, it follows that a non-aborting query of such an algorithm can be used to factor n . Hence, such queries can be answered efficiently, yielding the existence of an efficient emulator (without access to **Forger**) for any efficient algorithm.⁷

Extending the GT paradigm to our settings involves many complications. The main part of the GT paradigm is using the (hypothetical) attacker to reconstruct a random function using (too) short advice. This reconstruction involves emulating the attacker, where the key point is to do this without “wasting information”: any bit used to emulate, should give a bit of information about the (random) function. Doing the latter is quite easy for random functions; the answer to any query of the attacker gives the same amount of information about the function (i.e., the info that it maps the query input to the provided output). The only subtlety is that there are repeated queries (which are clearly wasteful), but handling such queries is easy: simply keep track of the query history on the emulation.

In our setting, however, things get much more complicated. To begin with, there might be non-repeating queries whose answers yield very little information about the random group $\pi(\mathbb{Z}_n^*)$ (and therefore about π). For instance, for some n ’s there are only four possible answers for the query $a^{\phi(n)/4}$ over $\pi(\mathbb{Z}_n^*)$. Thus, roughly speaking, the answer for this query contains only two bits of information about π . More generally, it appears that one can create much more intricate examples; e.g., when the answer to the query follows a very complicated distribution, based on the answers given so far.

An even more challenging task is proving the dichotomy that a non-aborting query can either be used to (efficiently) factor n , or implies a (too) short description of π . Handling the above challenges

⁷In addition, since non-aborting queries are *easy* to generate assuming that RSA is easy over $\pi(\mathbb{Z}_n^*)$, the above would immediately yield that RSA is equivalent to factoring over (random) $\pi(\mathbb{Z}_n^*)$, and thus over generic groups.

requires an intimate understanding of the algebraic structure of the group \mathbb{Z}_n^* , in particular of the set of solutions for linear equations over this group, and critically uses the fact that factoring is solvable in sub-exponential time [12, 37].

1.4 Further Research

The obvious open question is to try and extend our negative result to non-prime e 's. While the primality limitation seems merely as an artifact of our proof technique, it might indicate a possibility for instantiating a provably secure RSA-FDH! Another interesting question is to generalize our result to generic rings. (This extension, however, is currently not motivated by existing positive results.)

A broader research plan will be to use the proof technique we develop in this work (specifically, the adaptation of the Gennaro and Trevisan [15] short description paradigm to generic groups, see Section 1.3.1) for proving other uninstantiability results for other “group based” constructions. The immediate candidates are BLS signatures [6] and RSA-OAEP encryption scheme [3].⁸

Paper Organization

Section 2 contains basic notation and some basic linear algebra facts, where in Section 3 we formally define RSA-FDH and its security in the generic group model. Our main result, regarding the impossibility of existentially unforgeable RSA-FDH against unbounded number of signing queries, is proven in Section 4, where in Section 5 we prove our main technical lemma using the GT short description paradigm. Finally, in Section 6 we present our construction of an existentially unforgeable RSA-FDH scheme against a bounded number of signing queries.

2 Preliminaries

2.1 Notations

We use calligraphic letters to denote sets, uppercase for random variables and matrices, and lower-case for values. Given a random variable X , $X^{(t)} = (X_1, \dots, X_t)$ consists of t independent copies of X , where for a set \mathcal{S} , $\mathcal{S}^{(t)} = (\mathcal{S}_1, \dots, \mathcal{S}_t)$ denotes the t 'th direct product of \mathcal{S} . For integer $n \in \mathbb{N}$, we let $[n] = \{1, \dots, n\}$. Given a matrix $M \in \mathcal{U}_{t \times q}$ and a set of indices $\mathcal{I} \subseteq [q]$, the matrix $M_{\mathcal{I}} \in \mathcal{U}_{t \times |\mathcal{I}|}$ denotes the restriction of M to the columns in \mathcal{I} .

We let *poly* denote the set of polynomial, and let *PPT* denote the set of probabilistic algorithms (i.e., Turing machines) that run in *strict* polynomial time. A function $\mu: \mathbb{N} \rightarrow [0, 1]$ is *negligible* if $\mu(n) = n^{-\omega(1)}$, where *neg* denotes the family of negligible functions. Throughout the text we sometimes abuse notation and view *poly* and *neg* also as arbitrary members of the families they represent (e.g., we write $f(n) = \text{neg}(n)$ to denote $f \in \text{neg}$ and $f(n) > \text{neg}(n)$ for $f \notin \text{neg}$).

Given a random variable X taking values in a finite set \mathcal{U} , we write $x \leftarrow X$ to indicate that x is selected according to X . Similarly given a set $\mathcal{S} \subseteq \mathcal{U}$, we let $s \leftarrow \mathcal{S}$ denote that s is selected according to the uniform distribution on \mathcal{S} . We adopt the convention that when the same random variable occurs several times in an expression, all occurrences refer to a single sample. For example, $\Pr[f(X) = X]$ is defined to be the probability that when $x \leftarrow X$, we have $f(x) = x$. We write

⁸We mention that while the CCA proof of security for the RSA-OAEP in the RO model does not treat the RSA group as black box, this proof could be easily changed to be black box when given access to a generic group.

U_n to denote the random variable distributed uniformly over $\{0, 1\}^n$. A distribution ensemble $\mathcal{D} = \{D_k\}_{k \in \mathbb{N}}$ is of polynomial-length, if every element of D_k is described using $\text{poly}(k)$ bits. The statistical distance of two distributions P and Q over \mathcal{U} is defined as

$$\text{SD}(P, Q) := \frac{1}{2} \sum_{u \in \mathcal{U}} |P(u) - Q(u)|$$

We let \mathbb{P} denote the prime numbers, and for $n \in \mathbb{N}$ let \mathbb{Z}_n^* denote the group of elements in $[n]$ that are relatively prime to n , where multiplication mod n is the group operation.

2.2 Useful Linear Algebra Facts

Definition 2.1. Let M be an integer matrix with rows $\{v_1, \dots, v_t\}$, and let $e \in \mathbb{P}$.

- The rows of M are linearly dependent if there exist not all zeros real numbers $\{a_i\}_{i \in [t]}$, such that $\sum_{i \in [t]} a_i \cdot v_i = 0$.
- The rows of M are linearly dependent modulo e , if there exist not all zeros numbers in \mathbb{Z}_e $\{a_i\}_{i \in [t]}$, such that $\sum_{i \in [t]} a_i v_i = 0 \pmod{e}$.
- $\text{rank}(M)$ is the maximum number of rows of M that are linearly independent.
- $\text{rank}_e(M)$ is the maximum number of rows of M that are linearly independent modulo e .

The rank of any integer matrix M can be efficiently computed using Gaussian Elimination, which computes the reduced row Echelon form \widetilde{M} of M such that $\text{rank}(M)$ is the number of non zero rows of \widetilde{M} . Similarly we can compute $\text{rank}_e(M)$, but now every computation is done mod e . Notice that the latter is a well defined computation since every element in \mathbb{Z}_e has an inverse. Moreover, the analogue of many properties of $\text{rank}(M)$ are also true for $\text{rank}_e(M)$, because working mod e simply means working in another field (\mathbb{Z}_e instead of \mathbb{Q} or \mathbb{R}). In particular, we have the following:

Fact 2.2. The following holds for every $e \in \mathbb{P}$:

- Let $M \in \mathbb{Z}_{t \times \ell}$. If $\text{rank}_e(M) = s$, then there exists a (polynomial-time computable) submatrix $M' \in \mathbb{Z}_{s \times s}$ of M with $\det(M') \not\equiv 0 \pmod{e}$.
- Let $M \in \mathbb{Z}_{s \times s}$, then $\text{rank}_e(M) = s$ iff $\det(M) \not\equiv 0 \pmod{e}$.

3 RSA-FDH in the Generic Group Model

We start by recalling the standard notion of RSA-FDH signature scheme.

3.1 RSA-FDH Signature Scheme

Definition 3.1 (RSA-FDH). An RSA-FDH signature scheme Σ consists of the following triplet (KeyGen, Sign, Verify) of polynomial-time algorithms:

- On security parameter 1^k , KeyGen outputs a “public key” (n, e, h) , where n is a product of two primes, e is a element in $\mathbb{Z}_{\phi(n)}^*$ and h is a (hash) function, represented as an oracle-aided circuit, mapping values to \mathbb{Z}_n^* , and a “secret key” $d = e^{-1} \pmod{\phi(n)}$.

- On input $n \in \mathbb{N}$, $d \in \mathbb{Z}_{\phi(n)}^*$, a circuit h mapping values into \mathbb{Z}_n^* and a “message” m in the domain of h , **Sign** outputs the “signature” $h(m)^d \bmod n$.
- On input $n \in \mathbb{N}$, $e \in \mathbb{Z}_{\phi(n)}^*$, a circuit h mapping values into \mathbb{Z}_n^* , a “message” m in the domain of h and $\sigma \in \mathbb{Z}_n^*$, **Verify** outputs one iff $\sigma^e \equiv h(m) \bmod n$.

Now let us see what it means that an RSA-FDH signature scheme is existentially unforgeable under unbounded and bounded chosen message attack (EU-CMA-secure and t -EU-CMA-secure):

Definition 3.2 (security of RSA-FDH). *An oracle-aided algorithm F breaks the security of an RSA-FDH signature scheme $\Sigma = (\text{KeyGen}, \text{Sign}, \text{Verify})$, if*

$$\Pr_{(sk, pk) \leftarrow \text{KeyGen}(1^k)}[(m, \sigma) \leftarrow F^{\text{Sign}(sk, pk, \cdot)}(pk) : \text{Verify}(\sigma, m, pk) = 1 \wedge \text{Sign was not queried on } (sk, pk, m)] > \text{neg}(k) \quad (1)$$

A signature scheme Σ is EU-CMA-secure, if no (oracle-aided) PPT breaks its security, where Σ is t -EU-CMA-secure, if no PPT breaks its security when restricted to query **Sign** at most $t(k)$ times.

Remark 3.3 (Discussion). *Definition 3.1 allows the hash function h to be chosen as part of the public key, where h needs to be described as a circuit.⁹ In practice, however, a fixed hash function (e.g., SHA-1) defined over any string is used. Since any secure scheme (according to Definition 3.2) of the type used in practice trivially yields a secure scheme of the type considered in Definition 3.1, for the sake of impossibility results it suffices to consider Definition 3.1. Furthermore, a positive result according to Definitions 3.1 and 3.2, can be easily extended to output hash functions defined over all strings: first hash the message using a secure collision-resistant hash function (assuming such function exists), and then apply the bounded length scheme.*

Additional restriction of Definition 3.1 is that it requires the range of the hash function h to be a subset of \mathbb{Z}_n^ , where in practice the range of h is an arbitrary subset of \mathbb{Z}_n . Notice, however, that it is easy to forge the signature of a given message m with $h(m) \in \mathbb{Z}_n \setminus \mathbb{Z}_n^*$: if $h(m) = 0$, its signature is simply 0, otherwise $\gcd(h(m), n)$ implies a factorization of n , which in turn can be used to forge the signature of any message. It follows that by modifying the hash function used in a given RSA-FDH scheme to set $h(x) = 1$ whenever $h(x) \notin \mathbb{Z}_n^*$, one does not hurt the security of the scheme. In particular, for the sake of impossibility results it suffices to consider hash functions whose range is a subset of \mathbb{Z}_n^* .*

In the following we first formally define what we mean by generic group model, and then extend Definitions 3.1 and 3.2 to this model.

3.2 The Generic Group Model

There are different ways to interpret what it means to “treat the multiplicative RSA group \mathbb{Z}_n^* in a black-box way” (see Theorem 1.1). In the *generic algorithm model* due to Maurer [25], “generic” algorithms do not have a direct access to the group elements, but rather to a “black box” containing each element. The only operations allowed with these boxes, are the group operations (inverse and multiplication) and comparing two boxes for equality. The formulation we have chosen here, which we simply call the generic group model, is somewhat less abstract. An algorithm in our model

⁹Alternatively, h can be described as a Turing Machine running in time $\text{poly}(k)$, where k being the security parameter.

has an oracle access to a group isomorphic to \mathbb{Z}_n^* (specifically, the group resulting by renaming the elements of \mathbb{Z}_n^* according to some random permutation), through which it can perform the group operations. Unlike the generic algorithm model, however, in our model algorithms we do have access to the representation of the group elements and can manipulate them.

Since any algorithm that “works well” in the generic algorithm model (e.g., breaks the RSA assumption) implies an algorithm that works equally well in our model with respect to *any* group isomorphic to \mathbb{Z}_n^* , an impossibility result in our model implies a similar result in the model of Maurer. Namely, our model can be viewed as a model for proving impossibility results in the generic algorithm model.

We formally define our model as follows: for $n \in \mathbb{N}$, let $\Pi_{\phi(n)}$ be the set of all permutations from \mathbb{Z}_n^* to \mathbb{Z}_n^* . For $\pi \in \Pi_{\phi(n)}$, we denote with $\pi(\mathbb{Z}_n^*)$ the group induced by the group \mathbb{Z}_n^* where each element of \mathbb{Z}_n^* is renamed according to π . More specifically, the group operations over $\pi(\mathbb{Z}_n^*)$ are defined as follows: the inverse of $a \in \mathbb{Z}_n^*$ is $\pi((\pi^{-1}(a))^{-1} \bmod n)$ and the (group) product of $a, b \in \pi(\mathbb{Z}_n^*)$ is $\pi(\pi^{-1}(a) \cdot \pi^{-1}(b) \bmod n)$. By $\Pi(\mathbb{Z}_n^*)$ we denote the set of all groups $\pi(\mathbb{Z}_n^*)$, where $\mathcal{G} = \{G = \{G_n : G_n \in \Pi(\mathbb{Z}_n^*)\}_{n \in \mathbb{N}}\}$ (i.e., \mathcal{G} consists of sets of groups, where each set contains a group of $\Pi(\mathbb{Z}_n^*)$ for every $n \in \mathbb{N}$).

Abusing notation, we view $G \in \mathcal{G}$ as an oracle that given as input $n \in \mathbb{N}$ and one [resp., two elements] of G_n (i.e., of \mathbb{Z}_n^*), returns the group inverse [resp., the group product] of the element (if the oracle G is given as input an element outside G_n , it returns \perp), and let $G_n(\cdot) = G(n, \cdot)$. Given a sequence of group operations (e.g., $a \cdot b^{-1}$), we sometimes add the term $[G_n]$, to indicate that the operations are done with respect to the group G_n .

3.3 RSA-FDH Signature Schemes in the Generic Group Model

RSA-FDH signature schemes over $G \in \mathcal{G}$ is defined as follows:

Definition 3.4 (RSA-FDH signature scheme in the generic group model). *An RSA-FDH signature scheme $\Sigma^{\mathcal{G}}$ in the generic group model, consists of the following triplet of oracle-aided PPT’s (KeyGen, Sign, Verify):*

- *Given oracle access to $G \in \mathcal{G}$ and input 1^k , KeyGen^G outputs a “public key” (n, e, h) , where $n \in \mathbb{N}$ is a product of two primes, $e \in \mathbb{Z}_{\phi(n)}^*$ and h is a (hash) function, represented as an oracle-aided circuit mapping values into \mathbb{Z}_n^* , and a “secret key” $d = e^{-1} \bmod \phi(n)$.*
- *Given oracle access to $G \in \mathcal{G}$, input $n \in \mathbb{N}$, $d \in \mathbb{Z}_{\phi(n)}^*$, a circuit h mapping values into \mathbb{Z}_n^* and a “message” m in the domain of h , Sign^G outputs the “signature” $h^G(m)^d [G_n]$.*
- *Given oracle access to $G \in \mathcal{G}$, input $n \in \mathbb{N}$, $e \in \mathbb{Z}_{\phi(n)}^*$, a circuit h mapping values into \mathbb{Z}_n^* , a “message” m in the domain of h and $\sigma \in \mathbb{Z}_n^*$, Verify^G outputs one iff $\sigma^e \equiv h^G(m) [G_n]$.*

For $G \in \mathcal{G}$, we let Σ^G be the instantiation of $\Sigma^{\mathcal{G}}$ with G .

3.3.1 Security definition

The following definition realizes the security of bounded and unbounded existential unforgeability under chosen message attack of an RSA-FDH signature in the generic group model, analogously to that of the standard model.

Definition 3.5 (security of RSA-FDH signature in the generic group model). *An oracle-aided algorithm F breaks the security of an RSA-FDH signature scheme $\Sigma^G = (\text{KeyGen}, \text{Sign}, \text{Verify})$, if*

$$\Pr_{G \leftarrow \mathcal{G}, (sk, pk) \leftarrow \text{KeyGen}^G(1^k)} [(m, \sigma) \leftarrow F^{G, \text{Sign}^G(sk, pk, \cdot)}(pk) : \text{Verify}^G(\sigma, m, pk) = 1 \wedge \text{Sign was not queried on } (sk, pk, m)] > \text{neg}(k)$$

A signature scheme Σ^G is EU-CMA-secure, if no (oracle-aided) PPT breaks its security, where Σ^G is t -EU-CMA-secure, if no PPT breaks its security when restricted to query Sign at most $t(k)$ times.

Since we would like to rule out an EU-CMA-secure scheme, we ask the security proof of the scheme to be realized via a “black-box reduction” (as discussed in the introduction, we have very little chance to rule out a general proof of security). On the other hand, we consider a very weak form of such a reduction (which strengthens our main impossibility result).

Definition 3.6 (weakly black-box proof of security of RSA-FDH). *An RSA-FDH signature scheme $\Sigma^G = (\text{KeyGen}, \text{Sign}, \text{Verify})$ in the generic group model has a weakly black-box proof of security based on an assumption \mathbf{X} , if there exists an oracle-aided PPT R such that if \mathbf{X} is true, then the following holds: let F be a (possibly unbounded) adversary that breaks the security of Σ^G (see Definition 3.5), then for any PPT Emul there exists a polynomial-length distribution ensemble $\mathcal{D} = \{D_k\}_{k \in \mathbb{N}}$ such that*

$$\text{SD} \left((x, R^{G, F^G}(1^k, x)), (x, \text{Emul}^G(1^k, x)) \right)_{G \leftarrow \mathcal{G}, x \leftarrow D_k} > \text{neg}(k).$$

Remark 3.7 (Discussion). *Assuming that \mathbf{X} is true, the above intuitively asks that a security breach of Σ^G implies that a (slightly) non-trivial task can be performed. Specifically, an efficient oracle-aided algorithm can use a breaker of the scheme (in a black-box way) to sample some unsamplable distribution. Note that this is a very modest demand and indeed, it is implied by most black-box proofs of security one can think of.*

Consider for instance a proof of security R that black-box reduces the security of a scheme Σ^G to an assumption \mathbf{X} , say to the hardness of factoring. It follows that given any adversary F to Σ^G , the algorithm R^{G, F^G} factors integers too well. Assume without loss of generality that $R^{G, F^G}(x)$, if succeeds, outputs the factorization of the integer x , let D_k be the distribution that outputs an integer $x = pq$, for two randomly chosen k -bits prime, and consider the distribution $\xi_k = (x, R^{G, F^G}(1^k, x))_{G \leftarrow \mathcal{G}, x \leftarrow D_k}$ it induces. Now if factoring is hard, then there is no efficient Emul such that $(x, \text{Emul}^G(1^k, x))_{G \leftarrow \mathcal{G}, x \leftarrow D_k}$ is (even computationally) close to ξ_k . Namely, there is no weakly black-box proof of security for Σ^G based on factoring.

Now if factoring is hard, then there is no efficient Emul such that $(x, \text{Emul}^G(1^k, x))_{G \leftarrow \mathcal{G}, x \leftarrow D_k}$ is (even computational) close to ξ_k . Namely, there is no weakly black-box proof of security for Σ^G based on factoring.¹⁰

For completeness, we give the following natural adaptation of the RSA assumption to the generic group model.

¹⁰Note that there nothing specific to the hardness of factoring in the above discussion, but rather it seems to be generic to “any” hardness assumption (e.g., strong RSA).

Definition 3.8 (The RSA assumption in the generic group model). *There exists an oracle aided PPT Gen , which on input 1^k outputs (n, e) , where $n \in \mathbb{N}$ is a product of two primes and $\gcd(e, \phi(n)) = 1$ such that the following holds for any oracle-aided PPT A :*

$$\Pr_{G \leftarrow \mathcal{G}, (n, e) \leftarrow \text{Gen}^G(1^k), x \leftarrow \mathbb{Z}_n^*} \left[(A^G(1^k, n, e, x))^e \equiv x \pmod{G_n} \right] = \text{neg}(k).$$

4 There Exists No RSA-FDH with a Weakly Black-Box Proof

In this section we prove the main result of this paper.

Theorem 4.1 (Theorem 1.1, restated). *Let $\Sigma^{\mathcal{G}} = (\text{KeyGen}, \text{Sign}, \text{Verify})$ be an RSA-FDH signature scheme in the generic group model in which $\Pr_{G \leftarrow \mathcal{G}, (n, e, h) \leftarrow \text{KeyGen}^G(1^k)}[e \in P] > \text{neg}(k)$. If $\Sigma^{\mathcal{G}}$ has a weakly black-box proof of security based on (an assumption) X , then X is false.*

The proof of Theorem 4.1 immediately follows from the next lemma:

Lemma 4.2. *Let $\Sigma^{\mathcal{G}}$ be as in Theorem 4.1, then there exist a family of oracles $\text{Forger} = \{\text{Forger}_G\}_{G \in \mathcal{G}}$ and oracle-aided PPT's F and Emul , such that the following hold:*

1. *For every $G \in \mathcal{G}$, F^{G, Forger_G} breaks the security of $\Sigma^{\mathcal{G}}$.*
2. *For any oracle-aided PPT A and polynomial-length distribution ensemble $\mathcal{D} = \{D_k\}_{k \in \mathbb{N}}$:*

$$\text{SD} \left(A^{G, \text{Forger}_G}(1^k, x), \text{Emul}^G(1^k, x, \text{desc}(A)) \right)_{G \leftarrow \mathcal{G}, x \leftarrow D_k} = \text{neg}(k),$$

where $\text{desc}(A)$ denotes the description of the Turing Machine A .

Before proving Lemma 4.2, let us first use it for proving Theorem 4.1.

Proof of Theorem 4.1. Let $\Sigma^{\mathcal{G}}$ be an RSA-FDH scheme with $\Pr_{G \leftarrow \mathcal{G}, (n, e, h) \leftarrow \text{KeyGen}^G(1^k)}[e \in P] > \text{neg}(k)$. Assume that $\Sigma^{\mathcal{G}}$ has a weakly black-box proof of security based on (an assumption) X and let R be the algorithm guaranteed by this proof. Let Emul be the algorithm guaranteed by Lemma 4.2 with respect to $\Sigma^{\mathcal{G}}$. Lemma 4.2 yields that

$$\text{SD} \left((x, \tilde{R}^{G, \text{Forger}_G}(1^k, x)), (x, \text{Emul}^G(1^k, x, \text{desc}(\tilde{R}))) \right)_{G \leftarrow \mathcal{G}, x \leftarrow D_k} = \text{neg}(k)$$

for any polynomial-length distribution ensemble $\mathcal{D} = \{D_k\}$, where $\tilde{R}^{G, \text{Forger}_G}(\cdot) = R^{G, F^{\text{Forger}_G}}(\cdot)$. Letting $\tilde{F}^G(\cdot) = F^{G, \text{Forger}_G}(\cdot)$ and $\text{Emul}_R^G(\cdot) = \text{Emul}^G(\cdot, \text{desc}(\tilde{R}))$, it follows that

$$\text{SD} \left((x, R^{G, \tilde{F}^G}(1^k, x)), (x, \text{Emul}_R^G(1^k, x)) \right)_{G \leftarrow \mathcal{G}, x \leftarrow D_k} = \text{neg}(k)$$

for any polynomial-length distribution ensemble \mathcal{D} , yielding that X is false. \square

The rest of this section is devoted for proving Lemma 4.2. We find it more convenient, however, to prove a variant of Lemma 4.2 in which the emulator should work for any (polynomial-size) family of circuits. Namely, we prove the following lemma (in the following statement we only focus on the part that changed comparing to the original statement):

Lemma 4.3 (non uniform variant of Lemma 4.2).

2. The following holds for any (no input) polynomial-size family of oracle-aided circuits $\{C_k\}_{k \in \mathbb{N}}$:

$$\text{SD} \left(C_k^{G, \text{Forger}_G}, \text{Emul}^G(1^k, \text{desc}(C_k)) \right)_{G \leftarrow \mathcal{G}} = \text{neg}(k),$$

where C_k^{G, Forger_G} denotes the output of C_k given access to G and Forger_G , and $\text{desc}(C_k)$ denotes the description of C_k .

It is easy to see that the non-uniform lemma above yields the uniform Lemma 4.2. In Section 4.1 we define the family of oracles **Forger** and the efficient algorithm F that uses **Forger** to break any RSA-FDH scheme, in Section 4.2 we define the emulator **Emul**, where in Section 4.3 we put things together to prove Lemma 4.3.

4.1 The Forger

Recall (see Section 1.3) that **Forger** has to abort on “degenerated queries” — essentially those queries that are easy to produce over any group in $\Pi(\mathbb{Z}_n^*)$. To determine whether a query $(n, e, h, \{\sigma_i\}_{i \in [t]})$ is degenerated, we measure the complexity of the values $\{h(i)\}_{i \in [t]}$, as a function of the group queries done through their evaluations. Since the actual representation of these values is meaningless, we only focus on their representation as functions of the “hardwired terms” — the values used in the evaluation of $\{h(i)\}$ that first appear as an input to a group oracle call. Note that any group element used in the evaluation of $\{h(i)\}$, can be expressed using (only) these hardwired terms. To formally carry the above discussion, we describe the evaluation of $\{h(i)\}$ as a computation over the following group.

Definition 4.4 (The group **Symb**). *The elements of **Symb** are equivalent classes over the set of all finite strings “ $u_1^{a_1} \cdots u_k^{a_k}$ ”, where the u_i ’s are in \mathbb{N} and the a_i ’s are in \mathbb{Z} . The strings $c = “u_1^{a_1} \cdots u_k^{a_k}”$ and $c' = “u_1'^{a_1'} \cdots u_{k'}'^{a_{k'}'}$ ” are in the same equivalent class, if for every $w \in \mathbb{N}$ it holds that $\sum_{i \in [k]: u_i = w} a_i = \sum_{i \in [k']: u_i' = w} a_i'$. We identify a group element of **Symb**, with any string of its equivalent class. The unit element of **Symb** is the class identified by the empty string ε (or by “ $2^1 \cdot 2^{-1}$ ” etc), where $c \cdot c'$ is the equivalent class identified by the string “ $c \cdot c'$ ” and finally c^{-1} is the class identified by the string “ $u_1^{-a_1} \cdots u_k^{-a_k}$ ”.*

We naturally identify an element “ $u_1^{a_1} \cdots u_k^{a_k}$ ” \in **Symb** with an element of a given group V that contains $\{u_i\}_{i \in [k]}$, by identifying it with the result of the sequence of operations it induces over V (i.e., “ $u_1 \cdot u_2^{-1}$ ” with respect to $V = \mathbb{Z}_n^*$, is identified with $u_1 \cdot u_2^{-1} \pmod n$). To avoid confusion over which group a sequence of operations is taken, we typically suffix the sequence with the term $[V]$, indicating that it is done over the group V . It is clear that for any two strings u and u' that identify the same element of **Symb** (i.e., belong to the same equivalent class), it holds that $u \equiv u' \pmod{[V]}$ for any Abelian group V containing u and u' .

Next we use the above terminology to syntactically describe the computation of an oracle-aided circuit C , where we start by defining the hardwired terms determined by C ’s computation. To simplify notations, we assume that a circuit evaluates its gates one-by-one, and that its description determines this evaluation order.

Definition 4.5 (hardwired terms). Let C be an oracle-aided circuit, $G \in \mathcal{G}$ and $n \in \mathbb{N}$. The terms of C with respect to G_n , denoted $\text{Terms}_{C,G,n}$, are those values that appear either as input or as the answers to non-bottom queries of C to G_n (i.e., G_n returns a non-bottom value). The hardwired terms of C with respect to G_n , denoted $\text{HardWired}_{C,G,n}$ are those element inside $\text{Terms}_{C,G,n}$ that first appear as inputs to non-bottom queries to G_n . Finally, the answer terms are those terms that appear as answers to non-bottom queries (might intersect $\text{HardWired}_{C,G,n}$). We assume that the elements of each of the above sets are ordered according to the evaluation order.

We next use the syntax of the group Symb , to present any term as an expression of the hardwired terms.

Definition 4.6 (canonical form). Let C , G and n be as in Definition 4.5. The canonical form of $u \in \text{Terms}_{C,G,n}$ with respect to (C, G, n) , denoted $\text{Can}_{C,G,n}(u)$, is recursively defined as follows:

- if $u \in \text{HardWired}_{C,G,n}$, let $\text{Can}_{C,G,n}(u)$ be the element “ u^1 ” $\in \text{Symb}$.
- If u first appears as an output of a query $G_n(u', u'')$, let $\text{Can}_{C,G,n}(u) = \text{Can}_{C,G,n}(u') \cdot \text{Can}_{C,G,n}(u'') \text{ [Symb]}$.
- Similarly, if u first appears as an output of $G_n(u')$, we let $\text{Can}_{C,G,n}(u) = \text{Can}_{C,G,n}(u')^{-1} \text{ [Symb]}$.

Let $\{v_i\}_{i \in [\ell]} = \text{HardWired}_{C,G,n}$. Note that the canonical form of any $u \in \text{Terms}_{C,G,n}$ with respect to (C, G, n) , can be *uniquely* written as $\prod_{i \in [\ell]} v_i^{a_i} \text{ [Symb]}$, where a_i might be non zero, only if the hardwire term v_i appears before u does (in the evaluation order of C^G). Finally, the canonical forms of a set of terms, with respect to (C, G, n) , is compactly represented using the following matrix.

Definition 4.7 (canonical-form matrix). Let C , G and n be as in Definition 4.5, let $\{v_i\}_{i \in [\ell]} = \text{HardWired}_{C,G,n}$ and let $\mathcal{W} = \{u_i\}_{i \in [t]} \subseteq \text{Terms}_{C,G,n}$. The matrix $M^{G,n,C}(\mathcal{W}) \in \mathbb{Z}_{t \times \ell}$ is defined as $\{a_{ij}\}_{i \in [t], j \in [\ell]}$, assuming that $\text{Can}_{C,G,n}(u_i) = \prod_{j \in [\ell]} v_j^{a_{ij}} \text{ [Symb]}$ for every $i \in [t]$.

We are finally ready to define Forger_G .

Algorithm 4.8 (Forger_G).

Input: $q = (n, e, h, \{\sigma_i\}_{i \in [t]})$, where n , e and $\{\sigma_i\}_{i \in [t]}$ are integers, and h is an oracle-aided circuit.

Operation:

1. If $e \notin \mathbb{P}$, $|h| (= |\text{desc}(h)|) > t$ or for some $i \in [t]$ $h^G(i) \notin \mathbb{Z}_n^*$ or $h^G(i) \neq \sigma_i^e \text{ [G}_n]$, return \perp .
2. Let $M = M^{G,n,H}(\{h(i)\}_{i \in [t]})$ according to Definition 4.7, where H is the oracle-aided circuit that first evaluates $h^G(1), \dots, h^G(t)$ and then queries G_n on the answers (say asking for their inverses).
If $\text{rank}_e M < t$, return \perp .
3. Return $(h^G(0))^d \text{ [G}_n]$, where $d = e^{-1} \pmod{\phi(n)}$.

That is, Forger_G first checks that $\{\sigma_i\}_{i \in [t]}$ are valid signatures for the messages $\{1, \dots, m\}$ (with respect to G and the public key (n, e, h)) and that forging a signature for this public key is not easy (reflected in $\text{rank}_e M < t$). If satisfied, Forger_G forges a signature for 0.

Below we describe the PPT F that uses Forger_G for breaking the security of Σ^G .

4.1.1 The breaker F

The strategy of the algorithm F that uses **Forger** for breaking the security of Σ^G is simple: on input (n, e, h) it would like to use **Forger** on $(n, e, h, \{\sigma_i = \text{Sign}^G(n, e, i)\}_{i \in [t]})$ to forge the signature of 0. It might be the case, however, that **Forger** returns bottom on such input. Hence, F first checks by himself (without using **Sign** or **Forger**) whether **Forger** will return bottom on this input. If positive, it uses a straightforward approach (see below) for forging a message $k \in [t]$, without using **Forger** at all.

Algorithm 4.9 (F).

Input: $pk = (n, e, h)$

Oracles: $G \in \mathcal{G}_n$, $\text{Sign}^G(sk, pk, \cdot)$ and Forger_G .

Operation:

1. Let $t = |h|$ and let $M = M^{G,n,H}(\{h^G(i)\}_{i \in [t]})$ according to Definition 4.7, where H is as in Algorithm 4.8 (with respect to this h and t).
2. If $\text{rank}_e(M) = t$, return $\text{Forger}_G(n, e, h, \{\text{Sign}^G(sk, pk, i)\}_{i \in [t]})$.
Otherwise,
 - (a) Using Gaussian Elimination find $k \in [t]$ and a set $\{\lambda_i \in [e]\}_{i \in [t] \setminus \{k\}}$, such that for every $j \in [\ell]$ it holds that $M_{kj} \equiv \sum_{i \in [t] \setminus \{k\}} \lambda_i \cdot M_{ij} \pmod{e}$.
 - (b) Let $\gamma = \prod_{j \in [\ell]} v_j^{(M_{kj} - \sum_{i \in [t] \setminus \{k\}} \lambda_i \cdot M_{ij})/e} [G_n]$, where $\{v_i\}_{i \in [\ell]} = \text{HardWired}_{H,G,n}$ (see Definition 4.5).
 - (c) For every $i \in [t] \setminus \{k\}$, let $\sigma_i = \text{Sign}^G(sk, pk, i) \pmod{[G_n]}$ ($\equiv h^G(i)^d [G_n]$).
 - (d) Return $\sigma_k = \gamma^{-1} \cdot \prod_{i \in [t] \setminus \{k\}} \sigma_i^{\lambda_i} [G_n]$.

The following claim is immediate.

Claim 4.10. For every $G \in \mathcal{G}$, F^{G, Forger_G} breaks the security of Σ^G .

Proof. Let (n, e, h) be the public key of Σ^G with respect to to some $G \in \mathcal{G}$ with $e \in \mathcal{P}$. Assume that $\text{rank}(M) < t$ in the execution of F (otherwise the proof is immediate). In such a case, Step 3.(a) is guaranteed to succeed (and can be performed in polynomial time). It follows that

$$\begin{aligned}
 \sigma_k^e &\equiv \gamma^{-e} \cdot \prod_{i \in [t] \setminus \{k\}} h(i)^{\lambda_i} [G_n] \\
 &\equiv \gamma^{-e} \cdot \prod_{i \in [t] \setminus \{k\}} \prod_{j \in [\ell]} v_j^{\lambda_i \cdot M_{ij}} [G_n] \\
 &\equiv \gamma^{-e} \cdot \prod_{j \in [\ell]} v_j^{\sum_{i \in [t] \setminus \{k\}} \lambda_i \cdot M_{ij}} [G_n] \\
 &\equiv \gamma^{-e} \cdot h(k) \cdot \prod_{j \in [\ell]} v_j^{M_{kj} - \sum_{i \in [t] \setminus \{k\}} \lambda_i \cdot M_{ij}} [G_n] \\
 &\equiv \gamma^{-e} \cdot h(k) \cdot \gamma^e [G_n] \\
 &\equiv h(k) [G_n].
 \end{aligned}$$

Namely, σ_k^e is a valid signature of k , and since Sign^G was not asked on k , F breaks the security of Σ^G whenever $e \in P$. \square

4.2 The Emulator

Our task is to emulate a family of circuits $\{C_k\}$ with oracle access to $G \in \mathcal{G}$ and Forger_G , using only oracle access to G . We assume without loss of generality that $|C_k| \geq k$ (otherwise we emulate a padded version of this family) and omit k from the input parameter list of the emulator. We also assume without loss of generality that before calling Forger_G on input $(n, e, h, \{\sigma_i\}_{i \in [t]})$, C_k first query G on $\{\sigma_i\}$ (otherwise, we will emulate the circuit C'_k that does so).

Given a circuit C , $\text{Emul}^G(C)$ emulates the execution of a circuit C^{G, Forger_G} by forwarding the G -calls to G , and answering the Forger_G -calls using the following method: let $q = (n, e, h, \{\sigma_i\}_{i \in [t]})$ be a query that C makes to Forger_G , Emul first checks whether Forger_G returns bottom on this call (which it can do efficiently), and if positive returns bottom to C as well. Otherwise, Emul uses the query q and the description of C to factor n , and then uses this factorization to answer the query efficiently.

The interesting question is how can Emul use such a pair (C, q) to factor n efficiently? Let H and M^H as computed by $\text{Forger}_G(q)$, and let $M^{(H;C)} = M^{G,n,(H;C)}(\{\sigma_i\}_{i \in [t]}) \in \mathbb{Z}_{t \times \ell'}$, where the circuit $(H;C)$ first evaluates H and then C .¹¹ Namely, M^H represents the canonical form of $\{h(i)\}_{i \in [t]}$ induced by the (stand alone) computation of H , where $M^{(H;C)}$ represents the canonical form of the “signatures” $\{\sigma_i\}_{i \in [t]}$ induced by the computation of $(H;C)$. Since $(H;C)$ first starts by computing H , it follows that every hardwired term $u \in \text{HardWired}_{H,G,n} \cap \text{HardWired}_{(H;C),G,n}$ has the same index with respect to both ordered sets $\text{HardWired}_{H,G,n}$ and $\text{HardWired}_{(H;C),G,n}$. Hence, the promise that $\sigma_i^e \equiv h(i) [G_n]$ for every $i \in [t]$, yields the following with respect to $\{v_i\}_{i \in [\ell']} = \text{HardWired}_{(H;C),G,n}$:

$$\prod_{j \in [\ell]} v_j^{M_{ij}^H} \equiv \prod_{j \in [\ell']} (v_j^{M_{ij}^{(H;C)}})^e [G_n],$$

for every $i \in [t]$. Since G_n is selected at random, (at least intuitively) C could have satisfied the above equations only if they hold regardless of the choice of G_n . Namely, it is the case that

$$\sum_{j \in [\ell]} M_{ij}^H \equiv e \cdot \sum_{j \in [\ell']} M_{ij}^{(H;C)} \pmod{\phi(n)} \quad (2)$$

for every $i \in [t]$. On the other hand, the assumption that $\text{Forger}_G(q) \neq \perp$ yields that $\text{rank}_e M^H = t$. Therefore, Equation (2) is “far” from being satisfied modulo e . In our proof we show how to use this inconsistency to find a multiple of $\phi(n)$, and thus to factor n .

The following description of Emul realizes the above discussion. We start by recalling the following known factoring algorithms. The first one is useful for small n ’s (for which the above discussion does not hold), and the second one factors arbitrary larger n , given a multiple of $\phi(n)$ as an advice.

Theorem 4.11 (factoring small numbers, [12, 37]). *There exists a procedure Sef that on input $n \in \mathbb{N}$, runs in time $2^{O(\sqrt{\log n \log \log n})}$ and factors n with constant probability.*

¹¹Recall that we allow circuits to have a predetermined evaluating order.

Lemma 4.12 (factoring using multiple of $\phi(n)$). *We say that $z = (z_1, z_2) \in \mathbb{Z} \times \mathbb{N}$ is a factoring advice for $n \in \mathbb{N}$, if $z_1^{\log n} \cdot \prod_{p \in \mathbb{P}: p < z_2} p^{\log n}$ is a non-zero multiple of $\phi(n)$.*

*There exists a procedure **Factor** that on input (n, z_1, z_2) , runs in time $\text{poly}(z_2) \cdot \text{poly}(\log |nz_1|)$, and factors n with constant probability, assuming that $z = (z_1, z_2)$ is a factoring advice for n .*

Proof. We use the following known algorithm due to Miller [26]

Theorem 4.13 (Miller's algorithm [26, 37]). *There exists a procedure that on input $n \in \mathbb{N}$ and $\mu \in \mathbb{Z}$, runs in time $\text{poly}(\log |n\mu|)$, and if μ is a non-zero multiple of $\phi(n)$, it factors n with constant probability.*

By definition $\mu = z_1^{\log n} \cdot \prod_{p \in \mathbb{P}: p < z_2} p^{\log n}$ is a non-zero multiple of $\phi(n)$. Thus, Miller's algorithm on input (n, μ) , runs in time $\text{poly}(\log |n\mu|) = \text{poly}(z_2 \cdot \log |nz_1|)$ and factors n with constant probability. Finally, note that μ is easily computable in time $\text{poly}(z_2, \log n)$. \square

We are now finally ready to define **Emul**.

Algorithm 4.14 (**Emul**).

Input: An oracle-aided circuit C .

Oracle: $G \in \mathcal{G}$.

Operation:

*Emulate C^G while on every query $q = (n, e, h, \{\sigma_i\}_{i \in [t]})$ to **Forger** $_G$, return the following value to C :*

1. *If **Forger** $_G$ would return \perp on q , return \perp as well (and continue to the next query). Else,*

2. *Try to factor n by doing the following for $|C|$ times:*

*If $n \leq |C|^{\frac{\log |C|}{\log \log |C|}}$, execute **Sef** (n) .*

*Otherwise, execute **Factor** $(n, \det(Q_{C,G,q}), |C|^4)$, where $Q_{C,G,q}$ is according to Definition 4.15.*

3. *If factoring of n is successful, return $h^G(0)^d [G_n]$, where $d = e^{-1} \pmod{\phi(n)}$.*

Otherwise, abort.

.....

The matrix $Q_{C,G,q}$ is defined as follows:

Definition 4.15 (query matrix). *Let C be an oracle-aided circuit, $G \in \mathcal{G}$ and let $q = (n, e, h, \{\sigma_i\}_{i \in [t]})$ be the query asked by C^{G, Forger_G} to **Forger** $_G$. The matrix $Q_{C,G,q} \in \mathbb{Z}_{t \times t}$ is defined as follows:*

1. *If **Forger** $_G(q) = \perp$, set $Q_{C,G,q} = 0_{t \times t}$.*

Otherwise:

2. *Let $M^H = M^{G,n,H}(\{h(i)\}_{i \in [t]})$ according to Definition 4.7, where H is as in Algorithm 4.8 with respect to this h and t . (Since **Forger** $_G(q) \neq \perp$, the matrix M^H is well defined and of rank t .)*

3. Let $\mathcal{I} \subseteq [\ell]$ be the first subset of size t (from hereafter we assume some arbitrary order on such sets) with $\text{rank}_e(M_{\mathcal{I}}^H) = t$.¹²
4. Let $M^{(H;C)} \in \mathbb{Z}_{t \times \ell'}$ be the matrix $M^{G,n,(H;C)}(\{\sigma_i\}_{i \in [t]})$ according to Definition 4.7, where $(H;C)$ is the circuit that first evaluates H and then evaluates C .
5. Set $Q_{C,G,q} = M_{\mathcal{I}}^H - e \cdot M_{\mathcal{I}}^{(H;C)}$.

Note that in the code of **Emul** if **Sef** is called, and thus n is small, then it runs in time $\text{poly}(|C|)$. In addition, the running time of **Factor**, if called, is also in $\text{poly}(|C|)$. Thus, **Emul** runs in polynomial time.

Moreover, it is clear that the only case where the output of $\text{Emul}^G(C, n)$ differs from the output of C^G is when the former aborts. This means that for some query of C to **Forger**, the latter would not return \perp , but either (1) **Sef** failed, or (2) z was a factoring advice but **Factor** failed, or (3) z was not a factoring advice for n . As the first two cases happen with negligible probability (by Theorem 4.11 and Lemma 4.12), we only have to prove that the latter happens with negligible probability.

This is formally done in the following lemma, whose proof (done via the "short description paradigm") is the topic of Section 5.

Lemma 4.16. *A query $q = (n, \cdot)$ to **Forger** made by $C^{G \in \mathcal{G}, \text{Forger}_G}$ is unexpected, if*

- $\text{Forger}_G(q) \neq \perp$,
- $n > |C|^{\frac{\log |C|}{\log \log |C|}}$, and
- $(\det(Q_{C,G,q}), |C|^4)$ is not a factoring advice for n , where $Q_{C,G,q}$ is according to Definition 4.15.

The following holds for any oracle-aided circuit C :

$$\Pr_{G \leftarrow \mathcal{G}}[C^{G, \text{Forger}_G} \text{ asks Forger an unexpected query}] \leq \delta(|C|),$$

where $\delta(|C|) = 2^{-\log^2 |C|}$.

Apart from its role in the proof of Lemma 4.3 (see Section 4.3), Lemma 4.16 immediately reproves the following fact.

Corollary 4.17. *In the generic group model, the RSA assumption is equivalent to (the hardness of) factoring.*

Proof. We only sketch the proof. Clearly, if we can factor the integer n output by **Gen** (see Definition 3.8) with non-negligible probability, we can break the RSA assumption in the generic group model (by computing d such that $e^{-1} \equiv d \pmod{\phi(n)}$). For the other direction, consider the oracle-aided algorithm A (with oracle access only to $G \in \mathcal{G}$) that on input n , sets C to be the oracle-aided circuit that makes the single call $\text{Forger}(n, e, h, \{\sigma_i = a_i^d \cdot [G_n]\}_{i \in [h]})$, where $e = 3$, h be the function such that $h^G(i) = a_i$, where a_i is the i 'th element in \mathbb{Z}_n^* , and $d = e^{-1} \pmod{\phi(n)}$. Note that C is efficient under the assumption that RSA is easy. Finally, A applies the method of **Emul** to emulate C^G . It is easy to see that Forger_G does not return \perp on this call (since $\text{rank}_e M^{G,n,H}(\{h(i)\}_{i \in [t]}) = t$, see Algorithm 4.8). Hence, Lemma 4.16 yields that **Emul** aborts with negligible probability, and therefore A factors n with save but negligible probability. \square

¹²Remember that $M_{\mathcal{I}}^H \in \mathbb{Z}_{t \times t}$ is the restriction of M^H to the columns in \mathcal{I} .

4.3 Putting it Together

Proof of Lemma 4.3. Claim 4.10 yields that F^{G, Forger_G} breaks the security of Σ^G with respect to every $G \in \mathcal{G}$, so it is left to prove that $\text{Emul}^G(C_k)$ emulates C_k^{G, Forger_G} well.

Recall that $|C_k| \in \text{poly}(k)$, and that we assume without loss of generality that $|C_k| \geq k$. Theorem 4.11 and Lemma 4.12 yield that $\text{Emul}(C_k)$ answers all “expected” queries of C_k to Forger with probability $1 - |C_k| \cdot 2^{\Omega(k)} = 1 - \text{neg}(k)$, where Lemma 4.16 yields that C_k asks unexpected queries with only negligible probability over the choice of $G \in \mathcal{G}$. Hence, with save but negligible probability, $\text{Emul}^G(C_k)$ emulates C_k^{G, Forger_G} correctly. \square

5 Proving Lemma 4.16 via the Short Description Paradigm

To prove Lemma 4.16 we apply the Gennaro and Trevisan [15] “short description” paradigm (introduced in the realm of black-box reduction from one-way functions/permutations) in the Generic Group Model. Roughly speaking, [15] shows that if there exists a circuit C that inverts a random permutation $\pi \in \Pi_n$ too well, then the description size of such random permutation is noticeably below $\log(n!)$ bits. This derives a contradiction, since describing a random permutation of Π_n requires $\log(n!)$ bits.

Analogously, assume towards contradiction that there exists a circuit C violating Lemma 4.16. In a nutshell, we prove that if C finds an unexpected query $q = (n, \cdot)$ for some $G \in \mathcal{G}$, then C ’s queries reveal a system of equations that gives a lot of information about the permutation $\pi \in \Pi_{\phi(n)}$ that defines G_n . This yields that there exists a large set of permutations inside $\Pi_{\phi(n)}$, whose members can be described using a (much) shorter than the information theoretical bound, deriving a contradiction.

In the following we assume for simplicity that C^{G, Forger_G} makes a single call to Forger_G and then halts (this simplification is easily justified in Section 5.8), and denote this query by q_G . Since C can only ask a query $q = (n, \cdot)$ with $\log n \leq |C|$, an averaging argument yields that there exists $n > |C|^{\frac{\log |C|}{\log \log |C|}}$ such that

$$\Pr_{G \leftarrow \mathcal{G}}[\text{Break}(G, n)] > \delta(|C|)/|C|, \quad (3)$$

where $\text{Break}(G, n)$ equals one iff $q_G = (n, \cdot)$ and $(\det(Q_{C, G, q}), |C|^4)$ is not a factoring advice for n .

Given $G = \{G_i\}_{i \in \mathbb{N}} \in \mathcal{G}$ and $\pi \in \Pi_{\phi(n)}$, let G^π be the family of groups derived from G by replacing G_n with $\pi(\mathbb{Z}_n^*)$. The above yields that there exists $G \in \mathcal{G}$ such that

$$\Pr_{\pi \leftarrow \Pi_{\phi(n)}}[\text{Break}(G^\pi, n)] > \delta(|C|)/|C| \quad (4)$$

In the following we fix such G , let $\Pi'_{\phi(n)} \subseteq \Pi_{\phi(n)}$ be the set of permutations for which $\text{Break}(G^\pi, n) = 1$ and let $q^\pi := q_{G^\pi}$. Equation (4) yields that

$$\log |\Pi'_{\phi(n)}| \geq \log(\phi(n)!) + \log(\delta(|C|)/|C|) - 1 \quad (5)$$

We conclude the proof of Lemma 4.16 by showing how to use the assumed C for giving a much shorter description of $\Pi'_{\phi(n)}$, deriving a contradiction.

We first describe a rather simple attempt to give a short description of $\Pi'_{\phi(n)}$. While this attempt falls too short, it well illustrates the main ideas and the difficulties a task involves. In Section 5.4 we refine this approach to get the actual short description of $\Pi'_{\phi(n)}$.

5.1 Short description of $\Pi'_{\phi(n)}$ — First attempt

Let us start with few definitions. Let H be as in Algorithm 4.8 (with respect to $q = q^\pi$) and let $(H; C)$ be as in Definition 4.15, while omitting the (single) call of C to Forger_G (hence, $(H; C)$ only assumes oracle access to G).

For $\pi \in \Pi'_{\phi(n)}$ with $q^\pi = (n, e, h, \{\sigma_i\}_{i \in [t]})$, let $\text{HardWired}^\pi := \text{HardWired}_{(H; C), G^\pi, n}$, $\text{Terms}^\pi := \text{Terms}_{(H; C), G^\pi, n}$ and $\text{AnsTerms}^\pi = \text{Terms}^\pi \setminus \text{HardWired}^\pi$. In the following definition we identify a set of t “independent” terms inside Terms^π .

Definition 5.1 (independent terms). *For $\pi \in \Pi'_{\phi(n)}$, let $\{v_i\}_{i \in [\ell]} = \text{HardWired}^\pi$, let $M = M^{G^\pi, n, H}(\{h^{G^\pi}(i)\}_{i \in [t]})$ be as in Definition 4.7, and let $\mathcal{I} \subseteq [\ell]$ be the first subset of size t such that $\text{rank}_e(M_{\mathcal{I}}) = t$ as in Definition 4.15. We let IndepHardW^π and $\overline{\text{IndepHardW}}^\pi$ be the ordered sets $\{w_i\}_{i=1}^t = \{v_i\}_{i \in \mathcal{I}}$ and $\{\bar{w}_i\}_{i=1}^{\ell-t} = \{v_i\}_{i \notin \mathcal{I}}$ respectively.*

Fix $\pi \in \Pi'_{\phi(n)}$, and let $q^\pi = (n, e, h, \{\sigma_i\}_{i \in [t]})$. Recall that we assume without loss of generality that before making the call q^π , the circuit C evaluates x_i^e (over G_n^π) for every $i \in [t]$. Let $\text{Can}^\pi(\cdot) := \text{Can}_{(H; C), G^\pi, n}(\cdot)$, let $\{w_i\}_{i=1}^t = \text{IndepHardW}^\pi$, and let $\{\bar{w}_i\}_{i=1}^{\ell-t} = \overline{\text{IndepHardW}}^\pi$. For $i \in [t]$, assume that $\text{Can}^\pi(h(i)) = \prod_{j=1}^{\ell-t} \bar{w}_i^{\beta_{ij}} \cdot \prod_{j=1}^t w_j^{\alpha_{ij}}$ [Symb] and that $\text{Can}^\pi(\sigma_i) = \prod_{j=1}^{\ell-t} \bar{w}_j^{\beta'_{ij}} \cdot \prod_{j=1}^t w_j^{\alpha'_{ij}}$ [Symb]. Since $h(i) \equiv \sigma_i^e \pmod{\pi(\mathbb{Z}_n^*)}$ for every $i \in [t]$, it holds that

$$\prod_{j=1}^{\ell-t} \bar{w}_j^{\beta_{ij}} \cdot \prod_{j=1}^t w_j^{\alpha_{ij}} \equiv \prod_{j=1}^{\ell-t} \bar{w}_i^{e \cdot \beta'_{ij}} \cdot \prod_{j=1}^t w_j^{e \cdot \alpha'_{ij}} \pmod{\pi(\mathbb{Z}_n^*)}. \quad (6)$$

Or put it differently,

$$\prod_{j=1}^t w_j^{\alpha_{ij} - e \cdot \alpha'_{ij}} \equiv \prod_{j=1}^{\ell-t} \bar{w}_j^{e \cdot \beta'_{ij} - \beta_{ij}} \pmod{\pi(\mathbb{Z}_n^*)},$$

which yields the following set of equations over \mathbb{Z}_n^* :

$$\left\{ \prod_{j=1}^t \pi^{-1}(w_j)^{\alpha_{ij} - e \cdot \alpha'_{ij}} \equiv \prod_{j=1}^{\ell-t} \pi^{-1}(\bar{w}_j)^{e \cdot \beta'_{ij} - \beta_{ij}} \pmod{\mathbb{Z}_n^*} \right\}_{i \in [t]}. \quad (7)$$

We denote the above set of t equation by E^π , and define their “solution set” as follows:

Definition 5.2 (solution set). *Given a set of equations E over \mathbb{Z}_n^* , we let $\mathcal{S}(E)$ denote the (solution) set of all t -tuples over \mathbb{Z}_n^* , for which the equations of E still hold when the value of $(\pi^{-1}(w_1), \dots, \pi^{-1}(w_t))$ in the equations is replaced with any (but same for all equations) element of $\mathcal{S}(E)$.*

The following lemma helps us yield that the assumption that $(\det(Q_{C, G^\pi, q}), |C|^4)$ is not a factoring advice for n , implies that $\mathcal{S}(E^\pi)$ is rather small. Namely, E^π gives a lot of information about the preimages of IndepHardW^π (i.e., much smaller than the upper bound of $\phi(n)^t$).

Lemma 5.3. *Let $A = \{a_{ij}\}_{i,j \in [t]}$ be an integer matrix, let $\{b_i \in \mathbb{Z}_n^*\}_{i \in [t]}$, and let E be the following set of equations:*

$$\left\{ \prod_{j \in [t]} x_j^{a_{ij}} \equiv b_i \pmod{\mathbb{Z}_n^*} \right\}_{i \in [t]}.$$

Assuming that $\det A \neq 0$, then for every $c \in \mathbb{N}$ such that $(\det A, c)$ is not a factoring advice for n (see Lemma 4.12), there exists a prime $r \geq c$ such that $r \mid \phi(n)$ and $|\mathcal{S}(E)| \leq (\frac{\phi(n)}{r})^t$.

The proof of Lemma 5.3 is given in Section 5.9. However, the intuition is that an equation (consider the simple case of one unknown) of the form $x^a \equiv b \pmod{\mathbb{Z}_n^*}$ has “few” solutions, iff $\gcd(a, \phi(n))$ is small. In our case, remember that matrix Q_{C, G^π, q^π} corresponds to the coefficients of the exponents in E^π and the fact that $(\det(Q_{C, G^\pi, q^\pi}), c)$ is not a factoring advice implies that $\gcd(\det(Q_{C, G^\pi, q^\pi}), \phi(n))$ is “small”. For our needs, Lemma 5.3 yields the following upper bound on $|\mathcal{S}(E^\pi)|$ (also proven in Section 5.9):

Claim 5.4. *It holds that $|\mathcal{S}(E^\pi)| \leq (\frac{\phi(n)}{|C|^4})^t$.*

The following description tries to exploit the above fact to give a too short description for $\Pi'_{\phi(n)}$. It contains the information needed to emulate $(H; C)^{G^\pi}$, the preimages (with respect to π) of all terms in $\overline{\text{IndepHardW}}^\pi$, and the information needed to describe π outside of Terms^π . Since given the emulation and $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$, it is possible to reconstruct E^π , Claim 5.4 yields that relatively little information is needed to compute the preimages of all terms in IndepHardW^π . Using the above, the preimages of all terms in Terms^π can be computed, and thus (using the final part of the description) all of π can be reconstructed.

Description 5.5 (description of $\pi \in \Pi'_{\phi(n)}$).

Let $q^\pi = (n, e, h, \{\sigma_i\}_{i \in [t]})$. The description consists of the following parts defined with respect to the execution of $(H; C)^{G^\pi}$ as follows.

1. *Description of h .*
2. *Ordered set $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$, given in appearance order.*
3. *Ordered set AnswFull of all the answer terms, given in appearance order.*
4. *An index SolutionInd to the solution of $\mathcal{S}(E^\pi)$ induced by π .*
5. *A description Rest of the values of π over $\mathbb{Z}_n^* \setminus \pi^{-1}(\text{Terms}^\pi)$.*

We first show how to use the above description to reconstruct the value of π (yielding that this is indeed a good description), and then try to upper bound its length.

5.2 Reconstructing π

Lemma 5.6. *For any $\pi \in \Pi'_{\phi(n)}$, the description of π given in Description 5.5 (together with the fixed values of $G \in \mathcal{G}$ and the assumed circuit C) determines the value of π .*

Proof. Recall that saved but the description of π , we are given the value of the assumed circuit C and the value of the *fixed* set $G = (G_1, \dots, G_{n'}) \in \mathcal{G}$ (where n' is the maximal value accessed by $(H; C)$). We use the following reconstructing algorithm:

Description 5.7 (reconstruction).

1. Emulate the execution of $(H; C)^{G^\pi}$ as follows:
 - (a) $G_{n'}^\pi$ -queries with $n' \neq n$ are answered using G .
 - (b) G_n^π -queries are answered using AnswFull .
2. Use the above emulation to compute π as follows:
 - (a) Identify (using the emulation) the canonical forms of the terms of $(H; C)$ with respect to G^π and n , and use it to identify of the ordered sets IndepHardW^π and $\overline{\text{IndepHardW}}^\pi$ and the equations set E^π .
 - (b) Identify the solution set $\mathcal{S}(E^\pi)$ and use SolutionInd to determine $\pi^{-1}(w)$ for every $w \in \text{IndepHardW}^\pi$.
 - (c) Use the canonical form of Terms^π , and the values of $\pi^{-1}(\text{HardWired}^\pi)$ (determined by $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$ and $\pi^{-1}(\text{IndepHardW}^\pi)$) to compute $\pi^{-1}(\text{Terms}^\pi \setminus \text{HardWired})$.
 - (d) Use Rest to fully reconstruct π .

The only non-trivial step is Step 2(c). Recall that the canonical form c of a term $u \in \text{Terms}^\pi$, with respect to G^π and n , represents u as a multiplication of hardwired terms. Namely

$$c \equiv \prod_{i \in [\ell]} v_i^{a_i} [\text{Symb}],$$

where $\{v_i\}_{i \in [\ell]} = \text{HardWired}^\pi$. It follows that $u \equiv \prod_{i \in [\ell]} v_i^{a_i} [\pi(\mathbb{Z}_n^*)]$, and therefore

$$\pi^{-1}(u) \equiv \prod_{i \in [\ell]} \pi^{-1}(v_i)^{a_i} [\mathbb{Z}_n^*].$$

Hence, $\pi^{-1}(u)$ is determined by $\pi^{-1}(\text{HardWired}^\pi)$. □

5.3 Description length

The value of $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$ can be described using about $(\ell - t) \log \phi(n)$ bits (actually $\log \frac{\phi(n)!}{(\phi(n) - \ell + t)!} + 1$ bits suffice). AnswFull can be described using about $|\text{AnswFull}| \log \phi(n)$ bits. In addition, given Terms^π and $\pi^{-1}(\text{Terms}^\pi)$, Rest can be described using about $\log(\phi(n) - |\text{Terms}^\pi|) \approx (\phi(n) - |\text{Terms}^\pi|) \log \phi(n)$ bits. It follows that

$$\begin{aligned} \text{DescSize}(\pi) &\approx |h| + (|\text{AnswFull}| + \ell - t) \cdot \log \phi(n) + |\text{SolutionInd}| + (\phi(n) - |\text{Terms}^\pi|) \log \phi(n) \\ &\approx (\phi(n) - |\text{Terms}^\pi| + |\text{AnswFull}| + \ell - t) \cdot \log \phi(n) \\ &\quad + t \cdot (\log \phi(n) - 4 \log |C|), \end{aligned}$$

where the second inequality follows since $|h| \leq t$ and Claim 5.4.

Assuming that AnswFull does contains hardwired terms or reoccurrences of the same value, it follows that $|\text{AnswFull}| = |\text{Terms}^\pi| - \ell$. Therefore,

$$\begin{aligned} \text{DescSize}(\pi) &\approx (\phi(n) - t) \cdot \log \phi(n) + t \cdot \log \phi(n) - 4t \cdot \log |C| \\ &\approx \phi(n) \cdot \log \phi(n) - 4t \cdot \log |C| \\ &\leq \phi(n) \cdot \log \phi(n) - \Theta\left(\frac{\log^3 |C|}{\log \log |C|}\right). \end{aligned}$$

Where to derive the inequality we observed that $t \geq |h| \geq \log n$ otherwise hash function h could not have as input elements of \mathbb{Z}_n^* and by assumption $\log n \geq \frac{\log^2 |C|}{\log \log |C|}$. Comparing the above to Equation (5), it follows that the description of $\Pi'_{\phi(n)}$ is $\Omega(\log |C|)$ bits too short.

Unfortunately, the assumption about AnswFull we made above is not necessarily true. Firstly, AnswFull might contain values in HardWired^π , and secondly, there might be two (or more) queries in the execution of $(H; C)^{G^\pi}$ that yield the same output. Such “collisions” might inflate the size of AnswFull by at least $|C|$ bits, causing the above description to be too long.¹³

Let us elaborate on the above issue. Simple collisions that inflates the size of AnswFull are identical queries. This case, however, is easy to handle, since the identical queries are easily tractable and we only keep their answer in their first appearance in AnswFull . More generally, whenever the response of G_n^π is information theoretically implied by the description of π and the emulation till this point, we can omit it from the set AnswFull . Some collisions, however, are not information theoretically determined. For instance, the execution of $(H; C)^{G^\pi}$ might start with the following two queries:

$$G_n^\pi(w_1, w_2) \tag{8}$$

$$G_n^\pi(w_3, w_4) \tag{9}$$

where w_1, w_2, w_3, w_4 are different terms inside IndepHardW^π . Generally, for some permutations in $\Pi'_{\phi(n)}$ these queries collide (have the same answer), where this is not the case for other permutations. The point is that the output of the second query is *not* information theoretically determined by the output of the first query and the above description of π .

Remark 5.8 (collisions). *Somewhat ironically, collisions in the execution of $(H; C)^{G^\pi}$ (in particular those reflected in Equation (6)) are exactly what gave the hope that we can use C to compress $\Pi'_{\phi(n)}$. In the following section, we refine the above approach (and in particular the way collisions are treated) to get a description that is guaranteed to be short enough.*

5.4 Short description of $\Pi'_{\phi(n)}$ — The actual approach

The approach we used above for describing the execution of $(H; C)^{G^\pi}$ was too wasteful to be compensable by what we save on describing the preimages of IndepHardW^π . In the following we refine the way this information is described, yielding an overall shorter description size.

Collision queries, informally defined in the previous section, play an important role in the following discussion.

¹³Note that such penalty in the description length is payed, even if we only describe the second query in the collision via an index for the first query.

Definition 5.9 (collisions). *A G_n^π -query made through the execution of $(H; C)^{G^\pi}$ is a collision, if its answer term has already appeared in the evaluation order in another G_n^π -query either as a hardwired term or as the answer term to a previous query.*

We start by considering the equations induced by a prefix of the queries made by $(H; C)^{G^\pi}$. Generalizing Equation (7), the j 'th G_n^π -query made by $(H; C)^{G^\pi}$ yields either some equalities or $j-1$ inequalities over \mathbb{Z}_n . That is, let u_j be the j 'th answer term in Terms^π , and let $\prod_{j=1}^{\ell-t} \overline{w}_i^{\beta_{ij}} \cdot \prod_{j=1}^t w_j^{\alpha_{ij}}$ be its canonical form, where $\{w_i\}_{i=1}^t = \text{IndepHardW}^\pi$, and let $\{\overline{w}_i\}_{i=1}^{\ell-t} = \overline{\text{IndepHardW}}^\pi$. If the answer term u_j induces a collision with some term u_k , then this equality yields the equation

$$\prod_{i=1}^t \pi^{-1}(w_i)^{\alpha_{ij}-\alpha_{ik}} \equiv \prod_{i=1}^{\ell-t} \pi^{-1}(\overline{w}_i)^{\beta_{ik}-\beta_{ij}} \quad [\mathbb{Z}_n^*]. \quad (10)$$

Otherwise (no collision), it yields the following inequality for any $k < j$

$$\prod_{i=1}^t \pi^{-1}(w_i)^{\alpha_{ij}-\alpha_{ik}} \not\equiv \prod_{i=1}^{\ell-t} \pi^{-1}(\overline{w}_i)^{\beta_{ik}-\beta_{ij}} \quad [\mathbb{Z}_n^*]. \quad (11)$$

We denote by E_j^π the set of equations/inequalities induced by the first j queries of $(H; C)^{G^\pi}$. To avoid notational clattering, we assume that the j 'th answer term is also the j 'th term in Terms^π . It is also not hard to see that the value of $\mathcal{S}(E_j^\pi)$, and the execution of the first $j-1$ steps, determines the value of $k < j$ such that $u_j = u_k$, if such exists.

In the following description of π does not automatically add the answer term u_j to AnswFull (as done in the first attempt), but rather adds to the description the value γ_j that describes the solution set $\mathcal{S}(E_j^\pi)$ using $\mathcal{S}(E_{j-1}^\pi)$. Only if j 'th query is non colliding (as reflected in the description of $\mathcal{S}(E_j^\pi)$), the value of u_j is added to the set AnswFull .

Observe that the above description together with the value of h , $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$ and Rest (see Description 5.5), fully determines the value of π — In the emulation of $(H; C)^{G^\pi}$ one can use the above information to decide whether the j 'th query induces a collision or not (and with whom). If positive, it answers the query using the value of its colliding term. Otherwise, it answers the query using the next value in AnswFull .

The above description is also not wasteful; any information given in the description, gives (essentially) the same amount of info about π . To shorten the above description further (so that it is shorter than it should be), we use the following claim (proof given in Section 5.9.4), that is in the spirit (and indeed, implied by the same lemma) of the main observation made in our first attempt (Claim 5.4).

Claim 5.10 (informative indices). *There exists a set of indices $\text{InformativeIdx}_\pi = \{i_1, \dots, i_t\} \subseteq [| (H; C) |]$ of collision queries inside the execution of $(H; C)$, such that the following holds:*

$$\prod_{j=1}^t \frac{|\mathcal{S}(E_{i_{j-1}}^\pi)|}{|\mathcal{S}(E_{i_j}^\pi)|} \geq \left(\frac{1}{2} \cdot |C|^4\right)^t.$$

We modify the above description as follows: we add the description of $\text{InformativeIdx}_\pi$, and for each $j \in \text{InformativeIdx}_\pi$ remove the value γ_j (describing the solution set $\mathcal{S}(E_j^\pi)$ using $\mathcal{S}(E_{j-1}^\pi)$), and add the index of the colliding term u_k . All in all, we roughly add additional $2t \cdot \log |(H; C)|$

bits, and remove $4t \log |C|$. Since $|(H; C)| \leq 2|C|$, we save $\Omega(t \log |C|)$ from the description size, making the overall description too short.

The actual description of π is somewhat more complicated. In particular, this happens since the amount of information each γ_j contains might be fractional, and we cannot allow ourselves the price of rounding each γ_j . The solution we take is to bundle together the γ_j whose indices fall between two informative indices ($O(t)$ such bundles) and thus waste only t bits for rounding.

Description 5.11 (short description of $\pi \in \Pi'_{\phi(n)}$).

Let $q^\pi = (n, e, h, \{\sigma_i\}_{i \in [t]})$. The description consists of the following parts defined with respect to the execution of $(H; C)^{G^\pi}$ as follows.

1. Description of h .
2. Ordered set AnswFull of all non-colliding answer terms, in appearance order.
3. Ordered set $\pi^{-1}(\overline{\text{IndepHardW}^\pi})$, in appearance order.
4. Ordered index set IndepHardWIdx , describes where the terms in IndepHardW^π appear for the first time.
5. Description of the set $\text{InformativeIdx}_\pi = \{j_1, \dots, j_t\}$, defined in Claim 5.10.
6. Order index set CollisionIdx , contains the terms that collide with the answer items of $\text{InformativeIdx}_\pi$.
7. Ordered set $\{\gamma_1, \dots, \gamma_t\}$, where γ_i describes for $j_i \in \text{InformativeIdx}_\pi$, the set $\mathcal{S}(E_{j_{i-1}})$ using $\mathcal{S}(E_{j_0})$ (taking $\mathcal{S}(E_{j_0}) = \mathbb{Z}_n^{*t}$).
8. An index SolutionInd to the solution of $\mathcal{S}(E_{j_t})$ induced by π .
9. A description Rest of the values of π over $\mathbb{Z}_n^* \setminus \pi^{-1}(\text{Terms}^\pi)$.

The above description does not specify the way the set $\mathcal{S}(E_{j_{i-1}})$ is described using $\mathcal{S}(E_{j_0})$, and it is still unclear why the above description determines the value of π . We prove that in Sections 5.6 and 5.7, but first let us compute the length of the above description, under the assumption (also proven in Section 5.7) that it takes $\left\lceil \log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_0})|} \right\rceil + 1$ bits to describe γ_i .

5.5 Description length

Let us see how many bits are required at most to describe each part of the above description (the i -th item upper bounds the length of the i -th item above):

1. t
2. $\lceil \log \phi(n)^{|\text{AnswFull}|} \rceil + 1$
3. $(\ell - t) \cdot \log \phi(n) + 1$
4. $t \cdot \lceil \log 2|C| \rceil$ (since $|(H; C)| \leq 2|C|$)

5. $t \cdot \lceil \log 2|C| \rceil$
6. $t \cdot \lceil \log 2|C| \rceil$
7. $\sum_{j=1}^t (\log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_i-1})|} + 1)$
8. $\log |\mathcal{S}(E_{i_t})| + 1$
9. $\log (\phi(n) - |\text{AnswFull}| - \ell)! + 1$

Notice that

$$\begin{aligned}
(7) + (8) &= \sum_{j=1}^t (\log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_i-1})|} + 1) + \log |\mathcal{S}(E_{i_t})| + 1 \\
&= \sum_{j=1}^t (\log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_i-1})|} + \log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_i})|}) + \log |\mathcal{S}(E_{i_t})| \\
&\quad - \sum_{j=1}^t \log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_i})|} + t + 1.
\end{aligned}$$

Since $\mathcal{S}(E_{i_{j_0}}) = \mathbb{Z}_n^{*t}$, by Claim 5.10 we have

$$(7) + (8) = t \cdot \log \phi(n) - 4t \cdot \log |C| + O(t).$$

It follows that

$$\begin{aligned}
(2) + (3) + (7) + (8) &= (|\text{AnswFull}| + \ell) \cdot \log \phi(n) - 4t \cdot \log |C| + O(t) \\
&= \log \phi(n)^{|\text{AnswFull}| + \ell} - 4t \cdot \log |C| + O(t)
\end{aligned}$$

Since

$$(1) + (4) + (5) + (6) = 3t \cdot \log |C| + O(t),$$

we conclude that

$$\text{DescSize}(\pi) = \log (\phi(n) - |\text{AnswFull}| - \ell)! + \log \phi(n)^{|\text{AnswFull}| + \ell} - t \cdot \log |C| + O(t) \quad (12)$$

By Equation (5) $\log \left| \Pi'_{\phi(n)} \right| \geq \log(\phi(n)!) + \log(\delta(|C|)/|C|) - 1$. Hence, for every $\pi \in \Pi'_{\phi(n)}$ it holds that

$$\begin{aligned}
&\log \left| \Pi'_{\phi(n)} \right| - \text{DescSize}(\pi) \\
&\geq \log(\phi(n)!) + \log(\delta(|C|)/|C|) - 1 - \log (\phi(n) - |\text{AnswFull}| - \ell)! - \log \phi(n)^{(|\text{AnswFull}| + \ell)} \\
&\quad + t \cdot \log |C| - O(t) \\
&\geq \log (\phi(n) - |\text{AnswFull}| - \ell)^{|\text{AnswFull}| + \ell} - \log \phi(n)^{(|\text{AnswFull}| + \ell)} + \log(\delta(|C|)/|C|) \\
&\quad + t \cdot \log |C| - O(t).
\end{aligned}$$

Noticing that

$$\begin{aligned}
\log(\phi(n) - |\text{AnswFull}| - \ell)^{|\text{AnswFull}| + \ell} - \log \phi(n)^{|\text{AnswFull}| + \ell} &= \log \left(1 - \frac{|\text{AnswFull}| + \ell}{\phi(n)} \right)^{|\text{AnswFull}| + \ell} \\
&\geq \log \left(1 - \frac{(|\text{AnswFull}| + \ell)^2}{\phi(n)} \right) \\
&= -O(1),
\end{aligned}$$

and that $t \geq \log n \geq \frac{\log^2 |C|}{\log \log |C|}$ (as we argued in the previous section), we have that

$$\begin{aligned}
\log \left| \Pi'_{\phi(n)} \right| - \text{DescSize}(\pi) &\geq -\log^2 |C| - \log |C| + \Theta \left(\frac{\log^3 |C|}{\log \log |C|} \right) \\
&= \Omega(\log |C|),
\end{aligned}$$

Namely, our description of π is $\Omega(\log |C|)$ bits too short. In the next section prove that the description given in Description 5.11 uniquely determines π . Thus would yield a too short description of a permutation in $\Pi'_{\phi(n)}$, and thus would prove Lemma 4.16.

5.6 Reconstructing π

In this section we show how to use the description of π given in Description 5.11 to fully reconstruct π . Namely, we prove the following lemma:

Lemma 5.12. *For any $\pi \in \Pi'_{\phi(n)}$, the description of π given in Description 5.11 (together with the fixed values of $G \in \mathcal{G}$ and the assumed circuit C) determines the value of π .*

Proof. We use the following claim:

Claim 5.13. *For $\pi \in \Pi'_{\phi(n)}$, assume that the description of h , AnswFull , $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$ and IndepHardWIndx , as described in Description 5.11 are known. Then for any $j \in [| (H; C) |]$, the description of the set $\mathcal{S}(E_j)$ determines the first j steps of the execution of $(H; C)^{G^\pi}$, and vice versa.*

Proof. Assume that the claim holds for $j-1$, we use description of the first $j-1$ steps of $(H; C)^{G^\pi}$, to emulate its j 'th step as follows: using the code $(H; C)$ and the description of the first $j-1$ steps, we determine the j 'th query q_j . If q_j is a $G_{n'}^\pi$ -query with $n' \neq n$, we answer it using the (fixed) description of G , otherwise we do the following:

Let a_i be the answer of the i -query of $(H; C)^{G^\pi}$, and let c_i the value of the first $k < i$ such that $a_i = a_k$ (set it to \perp if no such k exists). The main observation (that we prove below) is that given the execution of the first $j-1$ steps, the value of $\mathcal{S}(E_j)$ determines the value of c_j and vice versa. It follows that the first j steps determine $\mathcal{S}(E_j)$, where for the other direction of the lemma, we answer the j 'th query as follows: we first compute c_j , and then answer with a_{c_j} if $c_j \neq \perp$, and with the next value of IndepHardWIndx otherwise.

For proving the above observation, we first notice that the value of E_{j-1} is determined by $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$ and IndepHardWIndx , and the execution of the first $j-1$ steps. Similarly, the value E_j is determined by the value c_j (and the above values). By the definition of E_j , different

values for c_j would imply different value for E_j . Moreover, such two different values for E_j cannot hold simultaneously — By definition, $c_j = k \in [j - 1]$ yields

$$\prod_{i=1}^t \pi^{-1}(w_i)^{\alpha_{ij}-\alpha_{ik}} \equiv \prod_{i=1}^{\ell-t} \pi^{-1}(\bar{w}_i)^{\beta_{ik}-\beta_{ij}} \quad [\mathbb{Z}_n^*],$$

but since a_k is the first collision, $c_j = k$ also yields that

$$\prod_{i=1}^t \pi^{-1}(w_i)^{\alpha_{ij}-\alpha_{ik'}} \not\equiv \prod_{i=1}^{\ell-t} \pi^{-1}(\bar{w}_i)^{\beta_{ik'}-\beta_{ij}} \quad [\mathbb{Z}_n^*],$$

for any $k' < k$ (where for $c_j = \perp$, the latter holds for $k = j$). Hence, the equations induced by different values of c_j conflict each other. It follows that the value of c_j induces a separation on the solution set $\mathcal{S}(E_{j-1})$, and thus the value of $\mathcal{S}(E_j)$ and c_j determine each other. \square

The above claim yields the following reconstruction algorithm for π :

Description 5.14 (reconstruction).

Emulate the execution of $(H; C)^{G^\pi}$ through the following t steps, where the i step emulates the execution of $(H; C)^{G^\pi}$ between the $j_{i-1} + 1$ and the j_i queries as follows:

1. *Compute $\mathcal{S}(E_{j_{i-1}})$ (using the emulation so far) and use it together with the value of γ_i , to compute $\mathcal{S}(E_{j_i-1})$.*
2. *Answer $G_{n'}^\pi$ -queries with $n' \neq n$ using the (fixed) description of G , where G_n^π -queries are answered (according to their order) as follows:*
 - $j < j_m$: *Use $\mathcal{S}(E_{j_{i-1}})$ to determine whether this is a collision query or not. If positive, return the colliding term value. Otherwise, return the next value in AnswFull .*
 - $j = j_m$: *Use CollisionIndx to find the colliding term, and return its value.*

The reconstruction continues as follows:

1. *Use SolutionInd and the value of $\mathcal{S}(E_{j_t})$ to compute $\pi^{-1}(\text{IndepHardW}^\pi)$.*
2. *Use the emulation and $\pi^{-1}(\text{HardWired})$ (determined by $\pi^{-1}(\overline{\text{IndepHardW}^\pi})$ and $\pi^{-1}(\text{IndepHardW}^\pi)$) to compute $\pi^{-1}(\text{Terms}^\pi \setminus \text{HardWired})$.*
3. *Use Rest to fully reconstruct π .*

Claim 5.13 yields that the emulation step is guaranteed to succeed, and the rest of the correctness of the rest of the reconstruction easily follows as in the case of our first attempt (see Section 5.2). \square

5.7 Describing the solution sets

Lemma 5.15. *For any $\pi \in \Pi'_{\phi(n)}$ and $j \in |(H; C)|$, the execution of $(H; C)^{G^\pi}$ until step j_{i-1} , and the values of AnswFull , $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$, IndepHardWIdx and $\text{InformativeIdx}_\pi$, determine a prefix free binary code $\mathcal{C} = \{cw_k\}_{k=1}^m$, such that the value of $\mathcal{S}(E_{j_{i-1}})$ is determined by cw_k for some $k \in [m]$ (and the above values), and $|cw_k| \leq \left\lceil \log \frac{|\mathcal{S}(E_{j_{i-1}})|}{|\mathcal{S}(E_{j_{i-1}})|} \right\rceil + 1$.*

Proof. We use the following lemma uses an encoding called Shannon-Fano (Shannon [35]) and its proof is in Section 5.9.

Lemma 5.16. *Let \mathcal{Y} be a finite set and let $\{\mathcal{Y}_k\}_{k=1}^m$ be disjoint subsets of \mathcal{Y} . Then there exists a prefix free binary code $\mathcal{C} = \{cw_k\}_{k=1}^m$, such that cw_k determines \mathcal{Y}_k for every $k \in [m]$, and $|cw_k| \leq \left\lceil \log \frac{|\mathcal{Y}|}{|\mathcal{Y}_k|} \right\rceil + 1$.*

For some $i \in [t]$, let $\mathcal{Y} = \mathcal{S}(E_{j_{i-1}})$. We will show that AnswFull , $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$, IndepHardWIdx and $\text{InformativeIdx}_\pi$ define a set $\{\mathcal{Y}_k\}_{k=1}^m$ of disjoint subsets of \mathcal{Y} such that for some $k \in [m]$, $\mathcal{Y}_k = \mathcal{S}(E_{j_{i-1}})$. Then using Lemma 5.16 we prove the claim.

For each $s = (s_1, \dots, s_t) \in \mathcal{S}(E_{j_{i-1}})$, we can do the following simulation of $(H; C)$ from query j_{i-1} until $j_i - 1$: for query $M \in \{j_{i-1}, \dots, j_i - 1\}$ of the form (u, u')

- If term u is indexed in IndepHardWIdx as the a_M -th independent hardwired term of $(H; C)^{G^\pi}$ and this is the first time this term appears in this emulation and the canonical form with respect to this emulation of term u' is $\prod_{i=1}^{a_M-1} w_i^{\alpha_i} \cdot \prod_{i=1}^{\ell'} \bar{w}_i^{\beta_i}$ [Symb], where w'_i is the hardwired term of this emulation indexed by the i -th index of IndepHardWIdx and $\{\bar{w}_i\}_{i \in [\ell']}$ are all the other hardwired terms of this emulation, then we compute the 'pseudo-preimage' of the output of this query as

$$s_{a_M} \cdot \prod_{i=1}^{a_M-1} s_i^{\alpha_i} \cdot \prod_{i=1}^{\ell'} \bar{\theta}_i^{\beta_i} \mod n,$$

where $\bar{\theta}_i$ is the i -th element of $\pi^{-1}(\overline{\text{IndepHardW}}^\pi)$. If this value collides with the 'pseudo-preimage' of some other term u'' of this emulation (which is computed analogously), then we take u'' as the response of this query, otherwise we take as response the corresponding element of AnswFull .

- If term u is indexed in IndepHardWIdx as the a_M -th independent hardwired term of $(H; C)^{G^\pi}$ and this is not the first time this term appears in this emulation, then we stop the emulation.
- The other cases are handled similarly to first case.

Now for every $s \in \mathcal{S}(E_{j_{i-1}})$, whose simulation was not stopped, let $E_{j_{i-1}}^s$ be the set of all equalities and inequalities of the emulation given by s with unknowns the preimages of the hardwired terms of this simulation indexed by IndepHardWIdx .

It is clear that for each $s' \in \mathcal{S}(E_{j_{i-1}}^s)$, it holds that $E_{j_{i-1}}^{s'} = E_{j_{i-1}}^s$, because in the emulations with respect to s and s' we will have the same collisions among the 'pseudo-preimages' and therefore these emulations are identical. Let $\{\mathcal{Y}_k\}_{k=1}^m = \{\mathcal{S}(E_{j_{i-1}}^s) : s \in \mathcal{S}(E_{j_{i-1}})\}$. Notice that the sets

$\mathcal{Y}_1, \dots, \mathcal{Y}_m$ are disjoint. If $s \in \mathcal{Y}_i \cap \mathcal{Y}_j$, then we should have $\mathcal{Y}_i = \mathcal{S}(E_{j_i-1}^s) = \mathcal{Y}_j$, which implies $i = j$. Moreover, it is clear that there exists a $k \in [m]$ such that $\mathcal{Y}_k = \mathcal{S}(E_{j_i-1})$. \square

5.8 Removing the simplifying assumption about C

In this section we need to justify the simplifying assumption that $C^{G, \text{Forger}}$ makes only a single call to **Forger** and then halts. Let C be a circuit such that

$$\Pr_{G \leftarrow \mathcal{G}}[\text{Break}(G, n)] > \delta(|C|),$$

and consider the circuit C' that before calling to **Forger** on $q = (n, \cdot)$, it first tries the approach that **Emul**(C) uses to emulate this call (i.e., using algorithms **Sef** and **Factor** as done in Algorithm 4.14). Specifically, since **Sef** and **Factor** are randomized algorithms, C' ties *all* possible random coins. If the factoring succeeds, C' uses it to answer the query by itself (as **Emul** does) and continue the execution, where otherwise it queries **Forger** and halts.

It is clear that C' success probability in making $\text{Break}(G, n) = 1$ is exactly that of C . Moreover, even though C' is much larger than C , the number of calls it makes to the oracle G is at most $|C|$ more than the number of calls done by C ; emulating a query to **forger**, involves at most one call to G (again see Algorithm 4.14). It follows that to index a query of C' to G , we need $\log |H; C| + O(1)$ bits (exactly as we assumed in the simplified case!). Thus, the proof above we gave under the simplifying assumption, holds also for the general case.

5.9 Missing Proofs

5.9.1 Proof of Lemma 5.3

Let

$$E = \left\{ \prod_{j=1}^t x_j^{a_{ij}} \equiv d_i \pmod{n} \right\}_{i \in [t]}$$

be a system of equations, where x_j 's are the unknowns and let us see how we can bound $|\mathcal{S}(E)|$. By the Fundamental Theorem of Finite Abelian Groups, we know that if $\phi(n) = \prod_{i=1}^s p_i^{\alpha_i}$ is the factorization of $\phi(n)$ then $\mathbb{Z}_n^* \cong \prod_{k=1}^s (\prod_{l=1}^{s_k} \mathbb{Z}_{p_k^{\beta_{kl}}})$, where $\sum_{l=1}^{s_k} \beta_{kl} = \alpha_k$ and $\mathbb{Z}_{p_k^{\beta_{kl}}}$ is the additive group of integers $\text{mod } p_k^{\beta_{kl}}$.

The equivalence of the groups implies a bijection between their group elements, such that each unknown x_j over \mathbb{Z}_n^* can be translated to an unknown $\{x_{klj}\}_{k \in [s], l \in [s_k]}$ over $\prod_{k=1}^s (\prod_{l=1}^{s_k} \mathbb{Z}_{p_k^{\beta_{kl}}})$, where each x_{klj} is an unknown over $\mathbb{Z}_{p_k^{\beta_{kl}}}$ and analogously for the d_i 's. Now each equation $\prod_{j=1}^t x_j^{a_{ij}} \equiv d_i \pmod{n}$ can be translated to the a set of independent equations, namely $\{\sum_{j=1}^t a_{ij} x_{klj} \equiv d_{kli} \pmod{p_k^{\beta_{kl}}}\}_{k \in [s], l \in [s_k]}$.

Let $E_{kl} = \{\sum_{j=1}^t a_{ij} x_{klj} \equiv d_{kli} \pmod{p_k^{\beta_{kl}}}\}_{i \in [t]}$. The bijection of the groups and the independence of each E_{kl} implies that

$$|\mathcal{S}(E)| = \prod_{k \in [s], l \in [s_k]} |\mathcal{S}(E_{kl})|. \quad (13)$$

Therefore, let us see how to bound the Solution Set of each E_{kl} .

The key observation is that Cramer's Rule still holds over linear equations modulo some integer. Namely, in our case, if $A = \{a_{ij}\}_{i,j \in [t]}$ and $A_j = \{a_{jfg}\}_{f,g \in [t]}$, where $a_{jfg} = \begin{cases} a_{fg} & \text{if } g \neq j \\ d_j & \text{if } g = j \end{cases}$ and $(\bar{x}_{kl1}, \dots, \bar{x}_{klt}) \in \mathcal{S}(E_{kl})$, then

$$\bar{x}_j \cdot \det A \equiv \det A_j \pmod{p_k^{\beta_{kl}}}$$

Therefore $|\mathcal{S}(E_{kl})| \subseteq |\mathcal{S}(\{\bar{x}_j \cdot \det A \equiv \det A_j \pmod{p_k^{\beta_{kl}}}\}_{j \in [t]})|$. Since each equation $\bar{x}_j \cdot \det A \equiv \det A_j \pmod{p_k^{\beta_{kl}}}$ has at most $\gcd(\det A, p_k^{\beta_{kl}})$ solutions, it holds that $|\mathcal{S}(E_{kl})| \leq (\gcd(\det A, p_k^{\beta_{kl}}))^t$. Hence, Equation (13) yields

$$|\mathcal{S}(E)| \leq \left(\prod_{k \in [s], l \in [s_k]} \gcd(\det A, p_k^{\beta_{kl}}) \right)^t \quad (14)$$

Now, if there exists a $k^* \in [s]$ such that $\gcd(\det A, p_{k^*}) = 1$, then

$$|\mathcal{S}(E)| \leq \left(\prod_{k \in [s] \setminus \{k^*\}, l \in [s_k]} \gcd(\det A, p_k^{\beta_{kl}}) \right)^t \leq \left(\frac{\phi(n)}{p_{k^*}^{\beta_{k^*l}}} \right)^t \leq \left(\frac{\phi(n)}{p_{k^*}} \right)^t \quad (15)$$

Furthermore, if $(\det A, c)$ is not a factoring advice for n and $\det A \neq 0$, then there exists a prime $r > c$ such that r is a factor of $\phi(n)$ but not a factor of $\det A$. Therefore, we can view r as p_{k^*} and Equation (15) implies that indeed $|\mathcal{S}(E)| \leq \left(\frac{\phi(n)}{r} \right)^t$.

5.9.2 Proof of Claim 5.4

In the case of system E^π , we observe that $Q_{C, G_\pi, q}$ is the corresponding matrix A from Lemma 5.3. Moreover, it holds $\det(Q_{C, G_\pi, q}) \neq 0$. This holds since $Q_{C, G_\pi, q} \equiv M_{\mathcal{I}}^{(H; C)^{G^\pi}, H} \pmod{e}$ (see Definition 4.15) and by assumption $\det(M_{\mathcal{I}}^{(H; C)^{G^\pi}, H}) \pmod{e} \neq 0$ (otherwise **Forger** would return \perp), we also have that $\det(Q_{C, G_\pi, q}) \pmod{e} \neq 0$, yielding that $\det(Q_{C, G_\pi, q}) \neq 0$.

Furthermore, since $(\det(Q_{C, G_\pi, q}), |C|^4)$ is not a factoring advice for n , we conclude that $|\mathcal{S}(E^\pi)| \leq \left(\frac{\phi(n)}{|C|^4} \right)^t$.

5.9.3 Proof of Lemma 5.16

By Shannon-Fano encoding we have that if X is a random variable taking values in a finite set \mathcal{U} , then there exists a prefix-free code which describes each $u \in \mathcal{U}$ spending at most $\log \Pr[X = u] + 1$ bits. Now if we let $\mathcal{U} = \{\mathcal{Y}_k\}_{k=1}^m$, since these are disjoint subsets of \mathcal{Y} , we can set $\Pr[X = \mathcal{Y}_k] = \frac{|\mathcal{Y}_k|}{|\mathcal{Y}|}$ and the lemma follows.

5.9.4 Proving Claim 5.10

Before proving this claim let us see some useful definitions and facts.

Definition 5.17. Let $E = \{e_1, \dots, e_\ell\}$ be a set where e_j is an equation over \mathbb{Z}_n^* of the form

$$\prod_{i=1}^t x_i^{a_{ij}} \equiv c_j \pmod{n},$$

with x_1, \dots, x_t the unknowns. We denote by $\text{Hom}(E)$ the corresponding homogeneous set of equations, i.e.

$$\prod_{i=1}^t x_i^{a_{ij}} \equiv 1 \pmod{n}$$

The following lemma shows the connection between a set of equations E and its homogeneous set $\text{Hom}(E)$:

Lemma 5.18. Let E , be a set of equations as in Definition 5.17, then $|\mathcal{S}(E)| = |\mathcal{S}(\text{Hom}(E))|$

Proof. We will prove the following: Let $\bar{y} = (\bar{y}_1, \dots, \bar{y}_t) \in \mathcal{S}(E)$, then $\mathcal{S}(E) = \{\bar{y} \circ x_0 : x_0 \in \mathcal{S}(\text{Hom}(E))\}$, where ' \circ ' denotes the group operation of $\mathbb{Z}_n^{*(t)}$. Let $\bar{z} = (\bar{z}_1, \dots, \bar{z}_t) \in \mathcal{S}(E)$, then by assumption we know that for every equation $\prod_{i=1}^t x_i^{a_{ij}} \equiv c_j \pmod{n}$ of E we have that $\prod_{i=1}^t \bar{y}_i^{a_{ij}} \equiv c_j \pmod{n}$ and $\prod_{i=1}^t \bar{z}_i^{a_{ij}} \equiv c_j \pmod{n}$. Consequently, we have that $\prod_{i=1}^t (\bar{y}_i^{-1} \cdot \bar{z}_i)^{a_{ij}} \equiv 1 \pmod{n}$, which implies that $\bar{y}^{-1} \circ \bar{z} \in \mathcal{S}(\text{Hom}(E))$ (where \bar{y}^{-1} is the group inverse of \bar{y} in $\mathbb{Z}_n^{*(t)}$). If we set $x_0 = \bar{y}^{-1} \circ \bar{z}$ we have that $\bar{z} = \bar{y} \circ x_0$. Moreover, if x_0, x'_0 are two distinct elements of $\mathcal{S}(\text{Hom}(E))$, then $\bar{y} \circ x_0 \neq \bar{y} \circ x'_0$, otherwise $x_0 = x'_0$. We conclude that $|\mathcal{S}(E)| = |\mathcal{S}(\text{Hom}(E))|$. \square

The next lemma shows an interesting property of $\text{Hom}(E)$, that we will use to measure $\mathcal{S}(\text{Hom}(E))$ and thus $\mathcal{S}(E)$ as well.

Lemma 5.19. If E is a set of equations over \mathbb{Z}_n^* as in Definition 5.17, then $\mathcal{S}(\text{Hom}(E))$ is a subgroup of $\mathbb{Z}_n^{*(t)}$.

Proof. The unit vector of $\mathbb{Z}_n^{*(t)}$ trivially belongs to $\mathcal{S}(\text{Hom}(E))$. Let $\bar{y} = (\bar{y}_1, \dots, \bar{y}_t), \bar{z} = (\bar{z}_1, \dots, \bar{z}_t) \in \mathcal{S}(\text{Hom}(E))$. By definition of $\mathcal{S}(\text{Hom}(E))$ we have that for every equation $\prod_{i=1}^t x_i^{a_{ij}} \equiv 1 \pmod{n}$ of $\mathcal{S}(\text{Hom}(E))$, $\prod_{i=1}^t \bar{y}_i^{a_{ij}} \equiv 1 \pmod{n}$ and $\prod_{i=1}^t \bar{z}_i^{a_{ij}} \equiv 1 \pmod{n}$. If we multiply these equations we have that $\prod_{i=1}^t (\bar{y}_i \cdot \bar{z}_i)^{a_{ij}} \equiv 1 \pmod{n}$, which shows that $\bar{y} \cdot \bar{z} \in \mathcal{S}(\text{Hom}(E))$. Moreover, $\prod_{i=1}^t (\bar{y}_i^{-1})^{a_{ij}} \equiv 1^{-1} \equiv 1 \pmod{n}$, which shows that \bar{y}^{-1} also belongs to $\mathcal{S}(\text{Hom}(E))$. The claim follows. \square

Therefore Lagrange Theorem yields the following:

Corollary 5.20. Let E be a set of equations as in Definition 5.17 and $E' \subseteq E$, then

$$\frac{|\mathcal{S}(\text{Hom}(E \setminus E'))|}{|\mathcal{S}(\text{Hom}(E))|} \in \mathbb{N}.$$

Proof. It follows from the fact that $\mathcal{S}(\text{Hom}(E))$ is a subgroup of $\mathcal{S}(\text{Hom}(E \setminus E'))$. \square

The next lemma shows that if E has few equations which reduce $|\mathcal{S}(E)|$ by a large factor, then most of these reduction is done by "few" equations.

Lemma 5.21. *Let E be a set of equations as in Definition 5.17, E_0 a subset of E such that $|\mathcal{S}(E_0)| = (\frac{\phi(n)}{\alpha \cdot r})^t$ for some prime $r \mid \phi(n)$ and some integer α and let $E|_i = \{e_1, \dots, e_i\}$, then there exist t indices i_1, \dots, i_t such that*

$$\prod_{j=1}^t \frac{|\mathcal{S}(E|_{i_{j-1}})|}{|\mathcal{S}(E|_{i_j})|} \geq r^t$$

Proof. Let $\alpha_i = \frac{|\mathcal{S}(E|_{i-1})|}{|\mathcal{S}(E|_i)|}$ for $i \in [\ell]$ and $\alpha_0 = \phi(n)^t$. By Lemma 5.18 we have that $\alpha_i = \frac{|\mathcal{S}(\text{Hom}(E|_{i-1}))|}{|\mathcal{S}(\text{Hom}(E|_i))|}$ and by Corollary 5.20 it has to be an integer. As $E_0 \subseteq E$ we know that $|\mathcal{S}(E)| = \frac{\phi(n)^t}{\alpha' \cdot r^t}$ for some $\alpha' \geq \alpha$, which has to be an integer because $|\mathcal{S}(E)| = |\mathcal{S}(\text{Hom}(E))|$ and $\mathcal{S}(\text{Hom}(E))$ is a subgroup of $\mathbb{Z}_n^{*(t)}$. In other words $\prod_{i=1}^\ell \alpha_i = \alpha' \cdot r^t$. The primality of r yields the existence of a set $\mathcal{J} \subseteq \{1, \dots, \ell\}$ of size t such that $\prod_{j \in \mathcal{J}} \alpha_j = \beta r^t$, for some integer β . The indices we are looking for are these in \mathcal{J} . \square

Now we want to see what happens to the solution set if E not only has equations, but inequalities as well. We split the inequalities into two categories.

Definition 5.22. *Let E be a set of equations as in Definition 5.17, s_c be an equation of the form $\prod_{i=1}^t x_i^{a'_i} \equiv c \pmod n$ and \tilde{s}_c the corresponding inequality, namely $\prod_{i=1}^t x_i^{a'_i} \not\equiv c \pmod n$. Then \tilde{s}_c is for E of*

- *r -Type I: if $\frac{|\mathcal{S}(E)|}{|\mathcal{S}(E \cup \{s_c\})|} < r$*
- *r -Type II: otherwise*

Remark 5.23. *Notice that given E the Type of an inequality \tilde{s}_c of the form $\prod_{i=1}^t x_i^{a'_i} \not\equiv c \pmod n$, only depends on the exponents a'_i 's and not on the right hand side c . This holds because for every $c, c' \in \mathbb{Z}_n^*$ $|\mathcal{S}(E \cup \{s_c\})| = |\mathcal{S}(\text{Hom}(E \cup \{s_c\}))| = |\mathcal{S}(\text{Hom}(E \cup \{s_{c'}\}))| = |\mathcal{S}(E \cup \{s_{c'}\})|$.*

The following lemma is useful.

Lemma 5.24. *Let E be a set of equations in Definition 5.17, s_1, s_2 two equations over \mathbb{Z}_n^* over the same unknowns, r a prime and a, b, c the largest integers such that $r^a \mid |\mathcal{S}(E)|$, $r^b \mid |\mathcal{S}(E \cup \{s_1\})|$ and $r^c \mid |\mathcal{S}(E \cup \{s_2\})|$. If $a = b$, then $r^c \mid |\mathcal{S}(E \cup \{s_1\} \cup \{s_2\})|$, with c being the largest such integer.*

Proof. Again we are going to use that $|\mathcal{S}(E)| = |\mathcal{S}(\text{Hom}(E))|$. As $\mathcal{S}(\text{Hom}(E))$ a group of size say m , by the Fundamental Theorem of Abelian Groups we know (as in the proof of Lemma 5.3) that if $m = r^a \prod_{i=1}^s p_i^{\alpha_i}$ is the factorization of m , then $\mathcal{S}(\text{Hom}(E)) \cong V \times W$, where $V \cong \prod_{j=1}^v \mathbb{Z}_{r^{a_j}}$, with $\sum_{j=1}^v a_j = a$ and $W \cong \prod_{i=1}^s (\prod_{k=1}^{s_i} \mathbb{Z}_{p_i^{\alpha_{ik}}})$, with $\sum_{k=1}^{s_i} \alpha_{ik} = \alpha_i$. Thus, we have that $|V| = r^a$ and $|W| = \prod_{i=1}^s p_i^{\alpha_i}$. Analogously, we have

- $\mathcal{S}(\text{Hom}(E \cup \{s_1\})) \cong V' \times W'$
- $\mathcal{S}(\text{Hom}(E \cup \{s_2\})) \cong V'' \times W''$
- $\mathcal{S}(\text{Hom}(E \cup \{s_1, s_2\})) \cong V''' \times W'''$

with $|V'| = r^b$ and $|V''| = r^c$ and $\gcd(r, |W'| \cdot |W''| \cdot |W''') = 1$.

Since $\mathcal{S}(\text{Hom}(E \cup \{s_1, s_2\})) = \mathcal{S}(\text{Hom}(E \cup \{s_1\})) \cap \mathcal{S}(\text{Hom}(E \cup \{s_2\}))$, it follows that $V''' \equiv V' \cap V''$ and $W''' \equiv W' \cap W''$. However, if $a = b$, then $V \equiv V'$, which implies that $V''' = V \cap V''$. Since $\mathcal{S}(\text{Hom}(E \cup \{s_2\})) \subseteq \mathcal{S}(\text{Hom}(E))$, we have that $V'' \subseteq V$ and therefore $V''' \equiv V''$. Thus, $|V'''| = r^c$ and we conclude that $r^c \mid |\mathcal{S}(\text{Hom}(E \cup \{s_1, s_2\}))|$. To prove that c is the largest such integer, we have to show that $|W' \cap W''|$ is not a multiple of r . But r is not a multiple of $|W'|$ (nor of $|W''|$) and $W' \cap W''$ is a subgroup of W' (and of W''), thus by Lagrange's Theorem r is not a multiple of $|W' \cap W''|$ either. The lemma follows from the fact that $|\mathcal{S}(E \cup \{s_1, s_2\})| = |\mathcal{S}(\text{Hom}(E \cup \{s_1, s_2\}))|$. \square

The next lemma shows that inequalities do not decrease the solution set by more than a factor of 2.

Lemma 5.25. *Let E be as in Definition 5.17, \tilde{E} a set of inequalities and e an equation over the same unknowns with E , r a prime factor of $|\mathcal{S}(E)|$, such that $r^\tau \mid \frac{|\mathcal{S}(E)|}{|\mathcal{S}(E \cup \{e\})|}$, where τ the largest such integer and $r \geq 2 \cdot |\tilde{E}|$. Then*

1. *If \tilde{E} only contains inequalities of r -Type I, then $r^\tau \mid \frac{|\mathcal{S}(E \cup \tilde{E})|}{|\mathcal{S}(E \cup \tilde{E} \cup \{e\})|}$ and*
2. *If \tilde{E} also contains inequalities of r -Type II, then $\frac{r^\tau}{2} \leq \frac{|\mathcal{S}(E \cup \tilde{E})|}{|\mathcal{S}(E \cup \tilde{E} \cup \{e\})|}$.*

Proof.

1. Let us prove it for the case $|\tilde{E}| = 1$. For every tuple $s = (b_1, \dots, b_t) \in \mathbb{Z}_n^{(t)}$ let s_c denote an equality of the form $\prod_{i=1}^t x_i^{b_i} \equiv c \pmod{n}$ and let \tilde{s}_c be the corresponding inequality, (i.e. $\prod_{i=1}^t x_i^{b_i} \not\equiv c \pmod{n}$). Let C_E^s be the set with all elements $c \in \mathbb{Z}_n^*$ such that s_c is consistent with E , namely there exists a tuple $(\bar{x}_1, \dots, \bar{x}_t) \in \mathcal{S}(E)$ such that $\prod_{i=1}^t \bar{x}_i^{b_i} \equiv c \pmod{n}$. By the definition of C_E^s we have:

- (a) $\mathcal{S}(E) = \bigcup_{c \in C_E^s} \mathcal{S}(E \cup \{s_c\})$
- (b) For every distinct $c, c' \in C_E^s$, $\mathcal{S}(E \cup \{s_c\}) \cap \mathcal{S}(E \cup \{s_{c'}\}) = \emptyset$ and
- (c) $|\mathcal{S}(E \cup \{s_c\})| = |\mathcal{S}(E \cup \{s_{c'}\})| = |\mathcal{S}(\text{Hom}(E \cup \{s_1\}))|$.

From property (a) we can see that for every $c \in C_E^s$ we have that $\mathcal{S}(E \cup \{\tilde{s}_c\}) = \bigcup_{c' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c'}\})$. Therefore, by Lemma 5.18 and properties (b),(c) it holds that if $\tilde{E} = \{\tilde{s}_c\}$ all we have to show is that $r^\tau \mid \frac{|\mathcal{S}(E \cup \{s_c\})|}{|\mathcal{S}(E \cup \{s_c\} \cup \{e\})|}$, because $\frac{|\mathcal{S}(E \cup \{s_c\})|}{|\mathcal{S}(E \cup \{s_c\} \cup \{e\})|} = \frac{\sum_{c' \in C_E^s \setminus \{c\}} |\mathcal{S}(E \cup \{s_{c'}\})|}{\sum_{c' \in C_E^s \setminus \{c\}} |\mathcal{S}(E \cup \{s_{c'}\} \cup \{e\})|} = \frac{|\bigcup_{c' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c'}\})|}{|\mathcal{S}(E \cup \{\tilde{s}_c\} \cup \{e\})|} = \frac{|\mathcal{S}(E \cup \{\tilde{s}_c\})|}{|\mathcal{S}(E \cup \{\tilde{s}_c\} \cup \{e\})|}$. As \tilde{s}_c is of r -Type I and r prime, if r^τ divides $|\mathcal{S}(E)|$ then r^τ also divides $|\mathcal{S}(E \cup \{s_c\})|$ and τ is the largest such integer. By Lemma 5.24, if τ' is the largest integer such that $r^{\tau'} \mid |\mathcal{S}(E \cup \{e\})|$, then τ' is also the largest integer such that $r^{\tau'} \mid |\mathcal{S}(E \cup \{s_c\} \cup \{e\})|$. The claim follows.

For the case of $|\tilde{E}| = 2$ with $\tilde{E} = \{\tilde{s}_c, \tilde{s}_{c'}\}$, we just observe that by Lemma 5.24, $\tilde{s}_{c'}$ is also an r -Type I inequality for $E \cup \{s_c\}$. Therefore, $r^t \mid \frac{|\mathcal{S}(E \cup \{s_c\} \cup \{\tilde{s}_{c'}\})|}{|\mathcal{S}(E \cup \{s_c\} \cup \{\tilde{s}_{c'}\} \cup \{e\})|} = \frac{|\sum_{c'' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c''}\} \cup \{\tilde{s}_{c'}\})|}{|\sum_{c'' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c''}\} \cup \{\tilde{s}_{c'}\} \cup \{e\})|} = \frac{|\bigcup_{c'' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c''}\} \cup \{\tilde{s}_{c'}\})|}{|\bigcup_{c'' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c''}\} \cup \{\tilde{s}_{c'}\} \cup \{e\})|} = \frac{|\mathcal{S}(E \cup \{\tilde{s}_c, \tilde{s}_{c'}\})|}{|\mathcal{S}(E \cup \{\tilde{s}_c, \tilde{s}_{c'}\} \cup \{e\})|} = \frac{|\mathcal{S}(E \cup \tilde{E})|}{|\mathcal{S}(E \cup \tilde{E} \cup \{e\})|}$. For the general case we continue arguing in the same way.

2. Let \tilde{E} only contain r -Type II inequalities. it follows that $|\mathcal{S}(E \cup \tilde{E})| \geq (1 - \frac{|\tilde{E}|}{r}) \cdot |\mathcal{S}(E)| \geq \frac{1}{2} |\mathcal{S}(E)|$. By the assumption of \tilde{E} we have that $|\mathcal{S}(E)| \geq r^\tau \cdot |\mathcal{S}(E \cup \{e\})| \geq r^\tau \cdot |\mathcal{S}(E \cup \tilde{E} \cup \{e\})|$. Combining them we get $\frac{r^\tau}{2} \leq \frac{|\mathcal{S}(E \cup \tilde{E})|}{|\mathcal{S}(E \cup \tilde{E} \cup \{e\})|}$.

For the general case, we see that $\mathcal{S}(E \cup \tilde{E})$ can be written as $\mathcal{S}(E \cup \tilde{E}_I \cup \tilde{E}_{II})$, where \tilde{E}_I only contains inequalities of r -Type I and \tilde{E}_{II} only inequalities of r -Type II. The above yields that for each inequality \tilde{s}_c , $\mathcal{S}(E \cup \{\tilde{s}_c\})$ can be written as a union of equally sized disjoint sets, i.e. $\bigcup_{c' \in C_E^s \setminus \{c\}} \mathcal{S}(E \cup \{s_{c'}\})$. Therefore $\mathcal{S}(E \cup \tilde{E})$ can be written as $\bigcup_{i \in \mathcal{I}} \mathcal{S}(E \cup E_i)$, for some sets $\{E_i\}_{i \in \mathcal{I}}$ that contain only equations and the sets $\mathcal{S}(E \cup E_i)$ are equally sized and disjoint. Now we have

$$\begin{aligned} \frac{r^\tau}{2} &\leq \frac{|\mathcal{S}(E \cup E_i \cup \tilde{E}_{II})|}{|\mathcal{S}(E \cup E_i \cup \tilde{E}_{II} \cup \{e\})|}, \quad \text{but} \quad \frac{|\mathcal{S}(E \cup E_i \cup \tilde{E}_{II})|}{|\mathcal{S}(E \cup E_i \cup \tilde{E}_{II} \cup \{e\})|} = \frac{\sum_{i \in \mathcal{I}} |\mathcal{S}(E \cup E_i \cup \tilde{E}_{II})|}{\sum_{i \in \mathcal{I}} |\mathcal{S}(E \cup E_i \cup \tilde{E}_{II} \cup \{e\})|} = \\ &= \frac{|\bigcup_{i \in \mathcal{I}} \mathcal{S}(E \cup E_i \cup \tilde{E}_{II})|}{|\bigcup_{i \in \mathcal{I}} \mathcal{S}(E \cup E_i \cup \tilde{E}_{II} \cup \{e\})|} = \frac{|\mathcal{S}(E \cup \tilde{E}_I \cup \tilde{E}_{II})|}{|\mathcal{S}(E \cup \tilde{E}_I \cup \tilde{E}_{II} \cup \{e\})|} = \frac{|\mathcal{S}(E \cup \tilde{E})|}{|\mathcal{S}(E \cup \tilde{E} \cup \{e\})|}. \end{aligned}$$

□

Now we are ready to prove Claim 5.10.

Proof of Claim 5.10. Let Q be number of queries of $(H; C)$. Since E^π is a subset of E_Q^π and since by Claim 5.4 $|\mathcal{S}(E^\pi)| \leq (\frac{\phi(n)}{r})^t$ for some prime $r|\phi(n)$ and $r \geq |C|^4$, by Lemma 5.21 we have that there exist t colliding queries such that $\prod_{j=1}^t \frac{|\mathcal{S}(E_{i_j-1}^\pi \setminus \tilde{E}_{i_j-1}^\pi)|}{|\mathcal{S}(E_{i_j}^\pi \setminus \tilde{E}_{i_j}^\pi)|} \geq (|C|^4)^t$, where \tilde{E}_j^π is the set of all inequalities derived in the first j queries. As for each \tilde{E}_j^π , we have that $|\tilde{E}_j^\pi| \leq 4|C|^2$ (an upper bound on $|\tilde{E}_j^\pi|$) we have that $|C|^4 \geq 2 \cdot |\tilde{E}_j^\pi|$ and we can use Lemma 5.25. The claim follows. □

6 A t -EU-CMA-secure RSA-FDH Signature Scheme

In this section we show the following under the RSA assumption (see below): for every polynomially-bounded integer function t there exists an efficient procedure KeyGen_t for which RSA-FDH scheme $\Sigma_t = (\text{KeyGen}_t, \text{Sign}, \text{Verify})$ is t -EU-CMA-secure. Furthermore, the reduction treats \mathbb{Z}_n^* and the potential adversary in a black-box way.

Definition 6.1 (RSA Assumption (in the Standard Model)). *There exist polynomial time procedures RSAKey and RSACHallenge such that*

1. RSAKey on input 1^k outputs an integer (n, p_1, p_2, e, d) , such that $n = p_1 p_2$, with $p_1, p_2 \in \mathbb{P}$, $\gcd(e, \phi(n)) = 1$ and $ed \equiv 1 \pmod{\phi(n)}$,
2. RSACHallenge on input (n, e) outputs $y \in \mathbb{Z}_n$, and
3. for any PPT A it holds that

$$\Pr_{(n, p_1, p_2, e, d) \leftarrow \text{RSAKey}(1^k), y \leftarrow \text{RSACHallenge}(n, e)} [x^e \equiv y \pmod{n} : x \leftarrow A(n, e, y)] = \text{neg}(k)$$

To construct the hash function of our RSA-FDH scheme, we use families of *cover free subsets*.

Definition 6.2 (cover-free subsets). *Let $\mathcal{S}_1, \dots, \mathcal{S}_n$ be subsets of a universe \mathcal{U} . These subsets are called t -cover free for any set of indices $\{i_1, \dots, i_t\}$ and for any index i_0 such that $i_0 \notin \{i_1, \dots, i_t\}$, it holds that $\mathcal{S}_{i_0} \not\subseteq \bigcup_{i \in \{i_1, \dots, i_t\}} \mathcal{S}_i$.*

The existence of such cover free subsets was proven by D'yachkov et al. [14], where the fact that we can construct them in polynomial time was proven by Kumar et al. [24].

Theorem 6.3 ([14, 24]). *There exist a polynomial-time algorithm CFGen and a constant $c > 0$ such that the following holds: for any integers n and t and a set \mathcal{U} of size $\lceil c \cdot t^2 \log n \rceil$, the family of subsets $\mathcal{S}_1, \dots, \mathcal{S}_n \subset \mathcal{U}$, where $\mathcal{S}_i = \text{CFGen}(n, t, \mathcal{U}, i)$, is t -cover free.*

Given a polynomial bounded integer function t , we assume without loss of generality that $t(k) = \text{poly}(k)$, and define the t -secure RSA-FDH signature scheme $\Sigma_t = (\text{KeyGen}_t, \text{Sign}, \text{Verify})$ as follows (we only define the key generator KeyGen_t , since the signer and verifier Sign and Verify are generic):

Algorithm 6.4 (KeyGen_t).

Input: 1^k .

Operation:

1. Let $(n, p_1, p_2, e, d) \leftarrow \text{RSAKey}(1^k)$.
2. Let $u = \lceil ct(k)^2 \log n \rceil$, where c is the constant from Theorem 6.3, and for $i \in [u]$ let $a_i \leftarrow \text{RSACHallenge}(n, e)$ and set $\mathcal{U} = \{a_i\}_{i \in [u]}$.
3. Construct the function $h_{\mathcal{U}} : \mathbb{Z}_n \mapsto \mathbb{Z}_n$, defined as $h_{\mathcal{U}}(m) = \prod_{i \in \mathcal{S}_m} a_i \bmod n$, where $\mathcal{S}_m := \text{CFGen}(n, t, \mathcal{U}, m)$.
4. Return $pk = (n, e, h_{\mathcal{U}})$ and $sk = d$.

Theorem 6.5 (Theorem 1.2, restated). *Under the RSA assumption Σ_t is t -EU-CMA-secure.*

Proof. Suppose that there exists an adversary F , that breaks $t(k)$ -times security of Σ_t with some non negligible probability $\delta(k)$. We show that there exists an PPT A which given black-box access to F breaks the RSA assumption. More specifically, A will be such that

$$\Pr_{(n, p_1, p_2, e, d) \leftarrow \text{RSAKey}(1^k), y \leftarrow \text{RSACHallenge}(n, e)} [x^e \equiv y \bmod n \mid x \leftarrow A^F(n, e, y)] \geq \Theta \left(\frac{\delta(k)}{t(k)^2 \log n} \right)$$

A is described as follows:

Algorithm 6.6. A

Input: $(1^k, n, e, y)$

Operation:

1. Let $u = \lceil ct(k)^2 \log n \rceil$, where c is the constant from Theorem 6.3, and for $i \in [u]$ let $b_i \leftarrow \text{RSACHallenge}(n, e)$.
2. For $i = 1, \dots, u$ set $a_i = b_i^e \bmod n$.
3. If $a_i \equiv y \bmod n$ for some $i \in [u]$, then return b_i .

4. Choose $\ell \leftarrow [u]$ uniformly at random.
5. Set $a_\ell = y$ and $\mathcal{U} = \{a_i\}_{i \in [u]}$
6. Query F on $(n, e, h_{\mathcal{U}})$, where $h_{\mathcal{U}}$ is as defined in Algorithm 6.4.
7. For each signing query of F on message m_i , where $i \in [t(k)]$ do
 - (a) If $\ell \notin \mathcal{S}_{m_i}$ respond to F with $\sigma_i = \prod_{i \in \mathcal{S}_{m_i}} b_i \mod n$ (where \mathcal{S}_{m_i} is as defined in Algorithm 6.4).
 - (b) Else abort.
8. If F returns a valid forgery σ on message m and $\ell \in \mathcal{S}_m$
 return $\sigma \cdot \prod_{i \in \mathcal{S}_m \setminus \{\ell\}} b_i^{-1} \mod n$

.....

If A stops at step 3 then it clearly succeeds. Below we assume that this is not the case.

To show that A^F succeeds with probability $\Theta(1/t(k)^2 \log n)$, consider the following experiment. Choose u random elements a_1, \dots, a_u of \mathbb{Z}_n and a random index $\ell \in [u]$. Query F on a random input $(n, e, h_{\mathcal{U}})$ chosen according to $\text{KeyGen}_t(1^k)$ and answer all signing requests. The success condition of this experiment is that F (1) succeeds in its forgery, (2) it requests the signatures of $m_1, \dots, m_{t(k)}$ such that $d \notin \bigcup_{j \in \{m_1, \dots, m_{t(k)}\}} \mathcal{S}_j$ and (3) outputs the signature of some m with $d \in \mathcal{S}_m$. If F succeeds we know that $m \notin \{m_1, \dots, m_{t(k)}\}$ and by the definition of subsets there exists one ℓ' such that $\ell' \notin \bigcup_{j \in \{m_1, \dots, m_{t(k)}\}} \mathcal{S}_j$ but $d' \in \mathcal{S}_m$. By assumption F succeeds in its forgery with probability $\delta(k)$ and with probability $1/u = \Theta(1/t(k)^2 \log n)$ we have that $\ell = \ell'$. Since these conditions are independent, the probability of success in the above experiment is $\Theta(\delta(k)/t(k)^2 \log n)$. If $\delta(k)$ is non-negligible then the latter probability is also non-negligible.

We argue that the probability of success of A is at least the probability of success of the above experiment. The input to F follows the same distribution as the output of $\text{KeyGen}_t(1^k)$. Whenever, F requests a signature σ_{m_i} of a message m_i such that $\ell \notin \mathcal{S}_{m_i}$, A returns a valid signature of m_i (since $(\prod_{i \in \mathcal{S}_{m_i}} b_i)^e \equiv \prod_{i \in \mathcal{S}_{m_i}} b_i^e \equiv \prod_{i \in \mathcal{S}_{m_i}} a_i \mod n$). If F forges m with a valid signature σ and $\ell \in \mathcal{S}_m$, then we have that $(\sigma \cdot \prod_{i \in \mathcal{S}_m \setminus \{\ell\}} b_i^{-1})^e \equiv h_{\mathcal{U}}(m) \cdot \prod_{i \in \mathcal{S}_m \setminus \{\ell\}} a_i^{-1} \equiv \prod_{i \in \mathcal{S}_m} a_i \cdot \prod_{i \in \mathcal{S}_m \setminus \{\ell\}} a_i^{-1} \equiv a_\ell \equiv y \mod n$. \square

Acknowledgments

We thank Thomas Holenstein and Ilya Mironov for very helpful conversations.
